7, 9, 11, and 13, and blood was collected from the orbital sinus for neutrophil counts. Nucleated cells in blood were counted using a Coulter counter (model ZF; Coulter Electronics, Hialeah, FL). Blood smears were stained with Wright-Giemsa for differential counts of leukocytes. A femur and spleen were collected from each mouse under sterile conditions. Using 23-gauge needles, femoral marrow cells or spleen cells were harvested in 2 or 5 mL of α -medium (Flow Laboratories, McLean, VA). The cells were counted using a Coulter counter and were washed by centrifugation at $400 \times g$. Granulocyte-macrophage progenitors (CFU-GM) in femoral marrow cells or in spleen cells were assayed in the semisolid agar culture system¹⁴ as follows: The cells (5×10^4 /plate) were plated in 0.5-mL aliquots of α -medium containing 20% fetal bovine serum (Flow Laboratories, North Ryde, NSW, Australia), 0.3% agar, and 10% WEHI-3 conditioned medium as a source of colony-stimulating factor.¹⁵ These cultures were carried out in 24-multiwell tissue-

Fig 2. Quantitative changes of neutrophils in blood. (A) CFU-GM in femoral bone marrow; (B) CFU-GM in spleen; and (C) CFU-GM in the mice after receiving 5-FU on day 0. A group of mice (○) were daily administered with rG-CSF (1×10^5 U/mouse/d) from day 0. Another group of mice (●) received only saline. Data represent mean value $\pm$ SE obtained from four mice in each data point.

culture plates (Corning 25820; Iwaki Glass, Japan). Duplicate cultures were made from each murine femur or spleen and were incubated at 37 °C in a humidified atmosphere of 5% CO₂ in air. After seven days of incubation, clonal colonies consisting of more than 50 cells were scored using an inverted microscope. In another experiment, blood (less than 30 μ L) was collected successively on days 9, 11, and 13 from the tail vein of each mouse for neutrophil counts.

RESULTS

The purified rG-CSF was found to be homogenous by SDS-polyacrylamide gel electrophoresis (Fig 1) and to have an apparent molecular weight of 17,400, whereas human G-CSF purified from cell culture⁷ migrated with an apparent molecular weight of 18,000. The purified rG-CSF had a specific activity of 1×10^8 U/mg of protein and contained less than 2.0 ng of endotoxin/mg of protein. This means that the *in vivo* studies were carried out in an almost endotoxin-free system.

Quantitative changes of neutrophils in blood and those of CFU-GM in femur or spleen of the mice injected with 5-FU are summarized in Fig 2. 5-FU caused severe neutropenia and a significant decrease of CFU-GM. More than 13 days were required for the full recovery from neutropenia in the 5-FU-treated mice. On the contrary, the daily administration of rG-CSF (1×10^5 U/d) to the 5-FU-treated mice caused a marked elevation in neutrophil counts on days 11 and 13 (313% and 1,019% of each paired control, respectively) as shown in Fig 2A. In comparison with the mild enhancing effect of rG-CSF on CFU-GM in femur (Fig 2B), rG-CSF administration showed a marked increase in CFU-GM in spleens on days 11 and 13 (498% and 278% of each paired control, respectively) as shown in Fig 2C. The recovery

from neutropenia in 5-FU-treated mice was accelerated by 5×10^4 to 2×10^5 units of rG-CSF in a dose-dependent manner (Fig 3).

DISCUSSION

Several laboratories have succeeded in large-scale production of hematopoietic factors from their cloned genes. Some of these recombinant factors are expected to be used as stimulators of hematopoietic restoration from anti-cancer drugs or irradiation-induced hematopoietic injury.¹⁶ Our observations described here support the possibility of therapeutic applications of rG-CSF in neutropenia caused by

Fig 3. Quantitative changes of neutrophils in blood of the mice after receiving 5-FU on day 0. Mice in each group (three mice/group) daily received 2×10^5 U/d of rG-CSF (○), 5×10^4 U/d of rG-CSF (□), or only saline (●). Blood less than 30 μ L was successively collected from tail vein of each mouse for neutrophil counts. Data represent mean value $\pm$ SE.

cancer chemotherapy. 5-FU in a dose of 200 mg/kg body weight caused severe neutropenia in mice. As shown in the results, it seemed that there were two stages in the process of granulopoietic recovery after being injured by 5-FU: The stage of regeneration of CFU-GM in bone marrow preceded

that of a CFU-GM increase in spleen. The administration of rG-CSF was much more effective in this second stage than in the first one. Thus, rG-CSF stimulated in vivo granulopoiesis to accelerate recovery from neutropenia in an endotoxin-free system.

Terminal Deoxynucleotidyl Transferase Expression Can Precede T Cell Receptor β Chain and γ Chain Rearrangement in T Cell Acute Lymphoblastic Leukemia

By James M. Greenberg and John H. Kersey

The nuclear enzyme terminal deoxynucleotidyl transferase (TdT) is thought to contribute to the diversity of certain immunoglobulin and T cell receptor gene rearrangements through the addition of random nucleotides at their variable (V)-joining (J) region junctions. An acute lymphoblastic leukemia (ALL) with an immature T cell phenotype (CD7⁺, CD5⁺, CD1⁺, CD2⁺, CD3⁺, CD4⁺, CD8⁺) was found to be TdT⁺ with germline immunoglobulin heavy chain, T

cell receptor β chain, and T cell γ chain genes. The data indicate that TdT expression can precede T γ and T β rearrangement during T lymphoid ontogeny consistent with its proposed association with the T cell receptor rearrangement process. Southern analysis of certain cases of T-ALL may not result in the detection of a monoclonal population of cells.

© 1987 by Grune & Stratton, Inc.

LYMPHOID progenitor cells in the bone marrow are known to express the nuclear enzyme terminal deoxynucleotidyl transferase (TdT).¹ This enzyme catalyzes the random addition of free deoxynucleotides onto the 3'-hydroxyl terminus of a nucleotide without the presence of a primer.² Experimental evidence suggests that TdT may be responsible for the insertion of extra random nucleotides between variable (V), diversity (D), or joining (J) regions during the rearrangement of immunoglobulin heavy chain or T cell receptor β chain genes during lymphoid ontogeny. These added sequences have been designated as N regions and are thought to contribute to the potential diversity of the antigen receptors encoded by these genes.^{3,4}

Three structurally related rearranging genes are associated with T cells. Two of these genes code for the polypeptide chains that compose the T cell receptor α/β heterodimer.⁴⁻⁷ The third, T γ , is rearranged and expressed prior to T β rearrangement during lymphoid ontogeny.⁸⁻¹⁰ Recent evidence suggests that T γ encodes a novel CD3-associated antigen receptor polypeptide on a subpopulation of human lymphocytes.^{11,12} T γ has also been shown to contain N regions that contribute to its diversity.¹³

A recent study indicates that TdT expression occurs during early T cell development.¹⁴ However, the precise temporal relationship between TdT gene expression and T cell receptor gene rearrangement during ontogeny is currently unknown. This sequence is of some importance in light of the emerging data on the early development of T γ rearrangement and expression reported by ourselves and others.⁸⁻¹² In this report, we describe an acute lymphoblastic leukemia of prothymocyte phenotype that has TdT expres-

sion but germline T γ , T β , and immunoglobulin genes. Our data suggest that TdT gene expression begins prior to T β and T γ rearrangement in T lymphoid progenitor cells. The results also indicate that early T cell leukemias may have germline T β and T γ genes.

MATERIALS AND METHODS

Case history. The leukemic cells described in this study were obtained from the peripheral blood and bone marrow of a 26-year-old female who presented with leukocytosis, thrombocytopenia, and anemia during preoperative evaluation for an elective cesarean section. Bone marrow and peripheral blood contained 95% and 80% lymphoblasts, respectively, at the time of diagnosis. There was no evidence of a thymic or mediastinal mass. The leukemic cells were myeloperoxidase, chloroacetate esterase, and Sudan black B negative. Cytochemical staining with nonspecific esterase and acid phosphatase was focal paranuclear positive suggestive of T lymphoblasts.¹⁵

A diagnosis of T cell acute lymphoblastic leukemia, FAB L2, was made on the basis of the morphologic, cytochemical, and immunophenotypic analysis of the leukemic lymphoblasts (Table 1). The patient received induction chemotherapy with vincristine, daunorubicin, prednisone, L-asparaginase, and methotrexate and has been maintained in remission with additional chemotherapy for 25 months.

Peripheral blood and bone marrow specimens were obtained following informed consent and utilized under guidelines established by the University of Minnesota Committee on the Use of Human Subjects in Research.

Cells. Suspensions of mononuclear cells containing leukemic lymphoblasts were prepared from peripheral blood or bone marrow by centrifugation through a discontinuous Ficoll-Hypaque (Pharmacia, Piscataway, NJ) gradient. The mononuclear cells at the Ficoll-Hypaque interface were resuspended in RPMI medium supplemented with 5% fetal calf serum. Cell suspensions were either used immediately or frozen in liquid nitrogen following the addition of 10% dimethyl sulfoxide to the medium.

Immunophenotypic analysis. Cells were analyzed for the presence of various cell surface antigens associated with hematopoietic cells (Table 1).¹⁶⁻³⁴ Following two washes in Ca⁺⁺, Mg⁺⁺-free phosphate-buffered saline, 10⁶ cells were mixed with a saturating concentration of murine or rabbit monoclonal antibody and allowed to incubate for 30 minutes at 4 °C. The cells were then washed twice and incubated for an additional 30 minutes at 4 °C with either a goat fluorescein-labeled antibody (FITC-G α M) that detected an initial murine monoclonal antibody or a goat rhodamine-labeled antibody (RITC-G α R) that detected an initial rabbit antibody. After three washes, the cells were analyzed with an automated fluorescence-activated flow cytometer (Ortho Spectrum III cytofluorograf, Ortho

Diagnostic Systems, Raritan, NJ, or FACS IV, Beckton-Dickinson, Mountain View, CA). Appropriate controls using cells stained only with FITC- α M were used to assess autofluorescence, and control ascites fluid was used to determine the extent of background staining. The flow cytometer generated a fluorescence profile for each antibody tested allowing the percentage of antigen-positive cells to be determined.

DNA extraction. High-molecular-weight DNA is extracted from bone marrow or peripheral blood mononuclear cells using a nuclei extraction technique as described by Bakhshi et al.³⁵ Isolated nuclei are lysed with sodium dodecyl sulfate (SDS) in the presence of proteinase K. The resultant viscous DNA solution is then extracted several times with phenol/chloroform/isoamyl alcohol (25:24:1) until the aqueous-organic interface is clear. Following a final extraction with chloroform/isoamyl alcohol (24:1), the DNA is ethanol-precipitated with 5 mol/L NaCl and resuspended in a small amount of TE buffer (10 mmol/L Tris Cl, 1 mmol/L EDTA, pH 7.4).

The concentration of DNA samples is determined by measurement of the OD₂₆₀. DNA samples extracted by the aforementioned methods routinely give OD₂₆₀:OD₂₈₀ ratios of 1.7 to 2.0.

Probes. Rearrangements of T γ are detected with an 800 bp genomic DNA probe containing sequences that hybridize to both joining regions of T γ . This probe was originally obtained from the laboratory of Dr J. Seidman, Harvard Medical School. It detects two germline EcoRI restriction fragments (3.3 kb and 1.8 kb).³⁶ Rearrangements of the β chain of the T cell receptor are detected with a 770 bp cDNA probe that recognizes the constant region of T β obtained from Dr T.W. Mak, Ontario Cancer Institute. The T β probe hybridizes to two germline EcoRI restriction fragments (11 kb and 4.0 kb) or one germline BamHI restriction fragment (24 kb).³⁷ Immunoglobulin heavy chain gene rearrangements were detected with a probe for the constant regions of the gene (C μ) obtained from Dr S.J. Korsmeyer, National Institutes of Health, Bethesda, MD. It detects a single 17 kb BamHI restriction fragment in germline DNA.³⁸

Southern blot analysis. Gene rearrangements are detected using the gel transfer technique first described by Southern.³⁹

High-molecular-weight genomic DNA is digested to completion using a selected restriction endonuclease. The restriction fragments are then size fractionated by electrophoresis through 0.8% agarose and transferred from the gel to a nylon filter (Zetabind, AMF Cuno) in 20 $\times$ SSC (1 $\times$ SSC is 150 mmol/L NaCl, 15 mmol/L sodium citrate, pH 7.4). After washing and prehybridization, the filters are hybridized in 50% formamide at 42 °C for 20 to 36 hours using probes labeled to high specific activity with ³²P by the random primer method.⁴⁰ The filters were then washed for 15 minutes in 2 $\times$ SSC, 0.1% SDS followed by one to two hours in 0.1 $\times$ SSC, and 0.1% SDS at the appropriate stringency for the probe being used. Filters were exposed to film (XAR-5, Kodak), with one intensifying screen for two to seven days at -70 °C.

RESULTS

Mononuclear cells from bone marrow and peripheral blood were subjected to immunophenotypic analysis. The results obtained with each monoclonal antibody are summarized in Table 1. The malignant lymphoblasts had an immunophenotypic profile corresponding to immature thymocytes or prothymocytes. The cells were strongly positive for TdT, the CD7 antigen (3A1), the CD5 antigen (T101), and the antigen detected by TA-1. Significant but lower levels of expression of the CD1 (OKT6) and CD2 (35.1) antigens were also detected. There was no significant staining with monoclonal antibodies directed against cell surface antigens associated with B lymphoid or myeloid lineage cells. Monoclonal antibody 3C5, which detects a cell surface antigen associated with very immature hematopoietic progenitor cells,³³ did not bind to the malignant cells.

Southern blot analysis was performed in order to detect rearrangements of IgH, T α , and T β in the malignant cells (Fig 1). With each probe, a germline pattern was detected when directly compared with germline DNA obtained from placenta. We verified the T β germline pattern seen in Fig 1 following EcoRI digestion by performing the same analysis with BamHI and HindIII (data not shown).

We, and others, have noted occasional instances when the T γ J probe detects rearrangement following BamHI digestion but not EcoRI.^{10,41} Therefore, patient DNA was also analyzed for T γ rearrangement following BamHI digestion and found to be germline.

DISCUSSION

Our results demonstrate that TdT expression can precede T cell receptor gene rearrangement in lymphoid ontogeny. This is, to our knowledge, the first report of a TdT-positive T lymphoid malignancy with germline T β and T γ and immunoglobulin genes. The notion that TdT expression may precede VJ (or VDJ) recombination is compatible with its proposed role in the generation of N region diversity during the gene rearrangement process.

The composite phenotype in this case is most consistent with that of an early thymocyte or prothymocyte. The lack of reactivity with a battery of myeloid and B lymphocyte lineage antigens, the lack of staining with myeloid cytochemical stains combined with expression of TdT, CD7, CD5, CD1, and CD2, all strongly argue for an early T lymphocyte lineage.

Fig 1. Southern blot analysis of T-ALL DNA. DNA was digested with *Eco*R1 and probed with T β (A); *Eco*R1 probed with T γ (B); and *Bam*H1 probed with C μ (C). Each T-ALL lane is accompanied by an identical Southern analysis of germline DNA obtained from human placenta. The sizes of the restriction fragments detected by each probe are indicated adjacent to each lane.

A recent report indicates that TdT expression as detected by an immunofluorescence assay may be spurious in PHA-stimulated peripheral blood mononuclear cells.⁴² Because cells were not available for a biochemical determination of TdT activity, we cannot rule out the possibility that our immunofluorescence assay may be detecting a cross-reacting protein lacking TdT activity. However, the morphologic and immunophenotypic characteristics of leukemias of an immature lymphoid phenotype have shown good concordance between immunofluorescence and biochemical determinations of TdT expression.⁴³

Recent reports suggest that CD7 (3A1) expression precedes T β rearrangement in T-ALL.^{14,44} Our findings indicate that certain T cell-associated cell surface antigens such as CD1, CD2, and CD5 as well as CD7 can be expressed prior to T γ as well as T β rearrangement. Although the function of these antigens is not known, their expression in a lymphoid cell with an immature (prothymocyte-type) T phenotype prior to gene rearrangement suggests that some or all may be involved in the thymic homing process.

The majority of lymphoid malignancies have a phenotypic counterpart in normal bone marrow, thymus, or peripheral

blood.⁴⁵ Lymphoid cells with immunophenotypic characteristics similar to those in our patient (CD7⁺, TdT⁺) have been detected in the peripheral blood and bone marrow of normal individuals.⁴⁶ Thus, the leukemic cells are likely an accurate representation of normal lymphopoiesis. However, occasional leukemias may not faithfully reflect early hematopoietic events.⁴⁷ The exceedingly low frequency of normal cells with this phenotype⁴⁶ makes DNA analysis of these cells not practical.

Rearrangements of T cell receptor genes (T β and T γ) can be detected by Southern blot analysis and have been used to detect clonal populations of malignant T lymphoid cells from bone marrow, peripheral blood, or lymph nodes.⁴⁸⁻⁵⁴ The results described above indicate that certain cases of T-ALL may not have detectable T cell receptor gene rearrangements even though they display a relatively unambiguous T phenotype. In such cases, Southern blot analysis to detect clonal populations of malignant cells will not provide useful information. Thus, adequate characterization of lymphohematopoietic malignancies continues to require a multidisciplinary approach including morphologic, immunophenotypic, and cytochemical analysis.

Marrow Purging in Autologous Bone Marrow Transplantation for T-Lineage Acute Lymphoblastic Leukemia: Efficacy of Ex Vivo Treatment With Immunotoxins and 4-Hydroperoxycyclophosphamide Against Fresh Leukemic Marrow Progenitor Cells

By Fatih M. Uckun, Kazimiera Gajl-Peczalska, Dorothea E. Meyers, Norma C. Ramsay, John H. Kersey, Michael Colvin, and Daniel A. Valleria

A lymphoblast progenitor cell assay was used to evaluate the antileukemic efficacy of marrow-purging protocols that employed intact ricin immunotoxins (IT) and 4-hydroperoxycyclophosphamide (4-HC) against clonogenic primary T-lineage marrow blasts freshly obtained from 12 T-lineage acute lymphoblastic leukemia (ALL) patients. Residual T-lineage blast colonies were observed after treatment with 1 µg/mL T101 (anti-CD5)-Ricin (R) + G3.7 (anti-CD7)-R in eight of 12 cases and after 100 µg/mL 4-HC

in six of nine cases. By comparison, a combination of IT and 4-HC proved very effective against T-lineage leukemic progenitor cells, and no residual blast colonies were observed in any of the eight cases studied. We conclude that future trials should consider combined treatment protocols such as IT + 4-HC for more effective purging of autologous marrow grafts.

© 1987 by Grune & Stratton, Inc.

THE PROGNOSIS of patients with T-lineage acute lymphoblastic leukemia (ALL) who experience bone marrow relapse while on maintenance therapy is poor. High-dose chemotherapy in combination with total body irradiation, followed by rescue with allogeneic or autologous bone marrow, is currently being investigated in a number of centers as an alternative to conventional chemotherapy for these high risk patients.¹⁻⁴

Autologous bone marrow transplantation (BMT) circumvents graft-v-host disease and results in a lower peritransplant morbidity or mortality than allogeneic BMT.¹ Autologous BMT does not require a histocompatible sibling donor and therefore a larger number of patients can meet the eligibility criteria for autologous than for allogeneic BMT. However, the likely presence of contaminating leukemic progenitor cells in the autologous marrow grafts, especially when the marrow is harvested during second or subsequent remission, or first remission prior to leukemic relapse, is a major concern.

A variety of immunologic^{5-10,13} and pharmacologic¹¹⁻¹³ strategies are being evaluated for effective purging of residual leukemic cells from autografts. Although most purging protocols have proved effective against established leukemic cell lines,⁵⁻¹¹ none have been tested against clonogenic marrow blasts taken directly from ALL patients. Therefore, there is no evidence that they can effectively eliminate residual ALL blasts from autografts. In the absence of data on fresh leukemic blast progenitors from ALL patients, it is difficult to evaluate and improve the efficacy of ex vivo marrow purging strategies.

Herein, we report the results of a preclinical study examining the efficacy of three distinct purging protocols at the level of T-lineage leukemic progenitor cells, using fresh leukemic marrow samples from 12 T-lineage ALL patients and blast progenitor cell assays. Specifically, we compared the antileukemic efficacy of (1) a cocktail of T101-R (anti-CD5) and G3.7-R (anti-CD7) IT, (2) 4-HC, as well as (3) a combination of both protocols, ie, combined immunochemotherapy against fresh clonogenic T-lineage ALL marrow blasts. We show that purging was not complete after IT or 4-HC treatment, and combined immunochemotherapy proved more effective than IT alone or 4-HC alone in many cases.

MATERIALS AND METHODS

Patient material. Twelve patients with T-lineage ALL were included in this study. Clinical and diagnostic data are summarized in Table 1. Bone marrow aspirate samples were obtained by conventional methods. Morphological classification was performed on Wright-Giemsa stained slides using a modification of the original French-American-British (FAB) classification. Blast cells were isolated by a single centrifugation on Ficoll-Hypaque (1.077 g/cm³). Marker analyses by indirect immunofluorescence (IF) and flow cytometry were performed using a panel of monoclonal antibodies (mAb) that define T-lineage (ie, 35.1, T101, G3.7) and B-lineage (ie, BA-1, BA-3) leukocyte differentiation antigens as previously described (Table 1).⁹

Colony assay for T-lineage ALL progenitor cells. Freshly obtained bone marrow blasts were cultured using a modification of a recently described assay system that allows reproducible proliferation and colony formation of fresh marrow blasts from patients with

*The immunological marker profiles of marrow blasts were determined by indirect IF and flow cytometry as described.⁹

Results are expressed as the percentage (%) of blasts positive for each marker.

B-cell precursor ALL.⁹ In brief, density gradient-isolated and adherent cell-depleted fresh marrow blasts from T-lineage ALL patients were suspended after treatment with various purging reagents in alpha-MEM (minimum essential medium) supplemented with 0.9% methylcellulose, 15% fetal calf serum (FCS), 15% platelet-rich fresh human plasma, 10% phytohemagglutinin-stimulated leukocyte-conditioned medium (PHA-LCM), 1,000 U/mL recombinant interleukin 2 (rIL-2) (generously provided by Dr Michael Widmer and the Immunex Corp, Seattle), and 50 μ mol/L 2-mercaptoethanol (2-ME). Duplicate 1-mL samples containing 10^5 blasts were cultured in 35-mm Petri dishes for seven days at 37 °C in a humidified 5% CO₂ atmosphere. On day 7, blast colonies containing >20 cells were counted using an inverted phase microscope with high optical resolution. Subsequently, all colonies were pooled for morphologic, cytochemical, and immunologic analyses of colony blasts. In this assay system, blast colony formation is linear with respect to numbers of cultured cells between 5×10^2 and 5×10^5 leukemic blasts per mL per Petri dish (data not shown). Thus far, colony assays have been performed on 30 T-lineage ALL patients, and blast colony formation was obtained in 20 cases with a median plating efficiency (PE) of 0.372% (Uckun et al, unpublished data). In the 12 cases included in this study, sufficient marrow blasts were obtained to evaluate the antileukemic efficacy of IT and 4-HC. The extent of cytotoxicity was expressed as Log Kill of T-lineage blast progenitor cells and was calculated as Log (PE of sham-treated blasts)/(PE of treated blasts).

Cytochemical and immunologic analysis of colony blasts. Cells from pooled colonies were deposited on slides by cytocentrifugation. The morphology of colony blasts was studied in Wright-Giemsa stained cytospin preparations. Blasts were evaluated for acid phosphatase (AP) activity using the conventional naphthol ASBI phosphoric acid-fast garnet GMC method. For surface marker analyses by indirect immunofluorescence, we used the mAb 35.1, anti-CD2 (T, p50); T101, anti-CD5 (T, p67); and G3.7, anti-CD7 (T, p41) as previously described.⁹ The terminal deoxynucleotidyl transferase (TdT) activity of colony blasts was determined by indirect IF on methanol-fixed cytospin preparations, using immunoadsorbent purified rabbit anti-TdT serum (20 μ g/mL) and FITC-conjugated goat F(ab')₂ antirabbit IgG (60 μ g/mL). These antisera were a generous gift of Dr Frederick Bollum, Uniformed Services University of Health Sciences, Bethesda, Maryland. Furthermore, a standard dual IF staining technique was employed to study the co-expression of nuclear TdT and surface T-lineage antigens. Briefly, methanol

fixed cytospin preparations were first subjected to indirect IF staining with rabbit anti-TdT serum and fluorescein-isothiocyanate (FITC)-conjugated goat F(ab')₂ antirabbit IgG. Subsequently, an equimolar cocktail of T101 and G3.7 mAb at 20 μ g/mL, followed by two washes in phosphate-buffered saline (PBS) and incubation with rhodamine-conjugated goat F(ab')₂ antimouse IgG + IgM (Tago, Burlingame, CA), was used to stain surface CD5 and CD7 determinants.

Source of purging reagents and ex vivo treatment conditions. IT against CD5 and CD7 determinants were synthesized at the University of Minnesota by conjugating T101 (IgG2a, anti-CD5) and G3.7 (IgG1, anti-CD7) mAb to intact ricin as described earlier.^{7,10} GK1.5, which recognizes the p52 surface determinant on murine T cells, was also linked to ricin as previously described⁷ and used as an irrelevant control IT. Details of the chemical conjugation procedure, immunoreactivity, cytotoxicity, and kinetics of action of the generated IT against leukemic T cell lines in protein synthesis inhibition and clonogenic assays, their potentiation by in vitro active cyclophosphamide congeners, as well as their effects on normal committed monopotent and multilineage bone marrow progenitor cells were published in previous reports.^{7,8,10} These IT were extremely toxic against leukemic T cell lines but only minimally toxic to normal bone marrow progenitor cells.^{7,10} Standard ex vivo treatment conditions with IT, 4-HC, and a combination of IT and 4-HC were established in earlier studies.^{7,11-13} They represent the clinical marrow purging protocols in autologous BMT for T-lineage ALL at Minnesota and Baltimore. In brief, cells (10^7 /mL) were treated with (1) 1 μ g/mL IT (an equimolar cocktail of T101-R and G3.7-R) for two hours at 37 °C in the presence of 200 mmol/L lactose (Minnesota protocol), (2) 100 μ g/mL 4-HC for 30 minutes at 37 °C (Baltimore protocol), or (3) a combination of 1 μ g/mL IT (two hours, 37 °C) and 100 μ g/mL 4-HC (30 minutes, 37 °C; 4-HC was added during the last 30 minutes of the IT treatment). Controls included leukemic marrow samples treated with (1) lactose only, (2) an equimolar cocktail of unconjugated T101, G3.7 mAb (0.750 μ g/mL), and free ricin (0.300 μ g/mL), (3) control IT GK1.5-R (1 μ g/mL), or (4) GK1.5-R (1 μ g/mL) + 4-HC (100 μ g/mL).

RESULTS AND DISCUSSION

Clinical and diagnostic features. Twelve patients with T-lineage ALL were studied. Patient data are summarized in Table 1. The patients ranged in age from 2 to 16 years

Fig 1. (A) Picture of part of Petri dishes containing compact clusters and colonies of T-lineage lymphoblasts cultured for seven days (x5). (B) Wright-Giemsa stained cells pooled from day 7 blast colonies in (A). Note the blast morphology with a basophilic cytoplasm, irregular nuclear membrane, prominent nucleoli, and vacuolation. (C) Colony blasts were evaluated for acid phosphatase activity. Note the focal paranuclear distribution of the stain. (D) Phase contrast. (E) Dual IF evaluation of colony blasts in the field shown in (D) for nuclear TdT and surface CD5 and CD7.

(median: 9 years). There were 11 males and one female. Two patients were in relapse and ten were newly diagnosed. Ten patients were morphologically classified as L1 ALL, while the subtype of the remaining two was L2. Bone marrow aspiration samples evaluated in the present study contained 75% to 100% blasts (median: 86.5%). No patient expressed the B-lineage-associated surface determinant CD24 recognized by BA-1 mAb. In contrast, the vast majority of cells from all patients reacted with 35.1, T101, and G3.7 mAb, which recognize distinct T-lineage differentiation antigens (Table 1). Only one of the 12 patients (unique patient number [UPN] 12) had >20% CD10/CALLA⁺ marrow blasts. These immunologic marker profiles are consistent with T-lineage affiliation.

Colony assays and analysis of colony blasts. Successful cultures were obtained from fresh marrow samples in all 12 cases. Day 7 blast colonies were compact and contained 50 to 500 cells (Fig 1, Table 2). The PE of blast progenitor cells varied from 0.049% (ie, 49 colonies per 10⁵ BM blasts) to 1.546% (ie, 1,546 colonies per 10⁵ BM blasts) with a median PE of 0.320% (Table 2). The cells from pooled colonies showed >95% viability, as estimated by trypan blue exclusion. They had blast morphology with a basophilic cytoplasm, irregular nuclear membrane, and prominent nucleoli (Fig 1). As shown in Fig 1, colony blasts displayed a strong AP activity in a predominantly focal paranuclear distribution. A minor component of the AP activity was in the form of coarse granules irregularly scattered in the cytoplasm. Blasts from pooled colonies showed a marked heterogeneity in expression of T-lineage-associated surface determinants (Table 2). Despite this heterogeneity, colony blasts in each case were found strongly positive for at least two T-lineage markers. Besides surface marker analyses, colony blasts were also tested for nuclear TdT activity and found strongly positive in all patients. In dual IF analyses, we found that 75% to 100% (median: 85%) of colony blasts in all studied cases were nuclear TdT-positive and strongly reacted with an equimolar cocktail of T101 and G3.7 mAb (Table 2, Fig

1). These marker profiles are consistent with T-lineage ALL.

Effects of intact ricin IT and 4-HC on fresh T lineage ALL blast progenitors. Table 3 shows the efficacy of the clinical Minnesota and Baltimore purging protocols against leukemic bone marrow progenitor cells freshly obtained from T-lineage ALL patients. Treatment with an equimolar cocktail of T101-R and G3.7-R at 1 μ g/mL (4.8 nmol/L) resulted in a significant inhibition of T-lineage blast colony formation in all 12 cases, whereas a mixture of free T101, G3.7 mAb (0.75 μ g/mL = 5 nmol/L), and unconjugated ricin (0.30 μ g/mL = 5 nmol/L) did not elicit a significant inhibition of blast progenitor cells. Control IT GK1.5-R did not affect the colony-forming ability of T-lineage ALL progenitor cells (Table 3). Furthermore, [T101-R + G3.7-R] IT-cocktail only minimally inhibited normal myeloid (ie, CFU-GM), erythroid (BFU-E, CFU-E), or early multilineage (CFU-GEMM) bone marrow progenitor cells at 1 μ g/mL (data not shown). These findings illustrate the selectivity and cell-type specificity of IT-mediated inhibition of T-lineage blast progenitors. The inhibition of leukemic progenitor cells ranged from 0.7 log (=79.7%) to >3.0 logs (=99.9%). However, purging was not complete, and residual T-lineage blast colonies were observed after this ex vivo marrow treatment regimen in eight of 12 cases (UPNs 1, 4-10). 4-HC was also a highly potent inhibitor of leukemic T-lineage progenitor cells. The inhibition of T-lineage blast progenitors after treatment with 100 μ g/mL (=341 μ mol/L) 4-HC ranged from 0.5 log (=64.7%) to 2.5 logs (=99.8%). However, purging was not complete, and residual blast colonies grew in six of nine cases (UPN 1, 4, 6, 8, 10, and 12). By comparison, in two independent experiments, 100 μ g/mL 4-HC completely inhibited CFU-GM, BFU-E, and CFU-GEMM from normal marrow samples (not shown).

A combination of [T101-R + G3.7-R] IT-cocktail (1 μ g/mL) and 4-HC (100 μ g/mL) was effective against leukemic progenitor cells from T-lineage ALL patients, and no residual blast colonies were observed after this treatment protocol

*Fresh T-lineage ALL blasts were cultured after various treatment regimens for seven days and assayed for colony formation as described in Materials and Methods. IT were used at 1 μ g/mL and 4-HC at 100 μ g/mL. Log Kill was calculated as Log (PE of sham-treated blasts)/(PE of treated blasts).

in any of the eight cases studied. In five of these eight cases (UPNs 1, 4, 6, 8, and 10), residual blast colonies were observed after treatment with [T101-R + G3.7-R] or 4-HC alone. In none of the eight cases was the combined protocol less effective than IT or 4-HC alone. The additional killing was specific and not due to some unexpected interactions between ricin IT and 4-HC, since irrelevant IT GK1.5-R only minimally affected the cytotoxicity of 4-HC against fresh clonogenic T-lineage ALL blasts (Table 3). As with 100 μ g/mL 4-HC alone, no in vitro hematopoietic colonies (ie, no CFU-GM-, BFU-E-, CFU-E, or CFU-GEMM-derived colonies) were obtained after treatment of normal marrow samples with this combination protocol in any of three independent experiments (data not shown). It may not be necessary to use 4-HC at as high as 100 μ g/mL if it is combined with IT. In four patients (UPN 1, 4, 6, and 8), no residual T-lineage blast colonies were observed after treatment with a ten-fold lower concentration of 4-HC (10 μ g/mL) and [T101-R + G3.7-R] (1 μ g/mL), a purging protocol that only minimally affected normal monopotent (CFU-GM, BFU-E, and CFU-E) or multilineage (CFU-GEMM) marrow progenitor cells (data not shown).

In summary, we have compared the antileukemic efficacy of clinical marrow purging protocols employing IT and 4-HC for autologous BMT in T-lineage ALL at the level of leukemic T-lineage marrow progenitor cells, using fresh marrow samples from 12 T-lineage ALL patients. These studies are of special interest because, to our knowledge, they represent the first analysis of the antileukemic efficacy of clinical purging protocols against fresh clonogenic ALL blasts. Two major findings are that (1) leukemic marrow progenitor cells from T-lineage ALL patients were quite sensitive to the lethal actions of ricin and 4-HC, and (2) an intact ricin IT-cocktail directed against CD5 and CD7 surface determinants, as well as 4-HC, could efficiently kill

T-lineage blast progenitors. Nevertheless, our findings also indicate that these purging protocols may be suboptimal, and combined immunochemotherapy may be a more effective purging strategy in autologous BMT for T-lineage ALL. These data are consistent with and further extend the published experience on the clinical potential of combined purging protocols for autologous BMT in ALL.^{7,11,13,14} The leukemic T-lineage progenitor cell assay described in this paper provides a basis for future comparative studies of different clinical purging protocols. Despite its obvious advantages over clonogenic assays which employ homogeneous cell lines, this colony assay is limited in its sensitivity because of the low plating efficiency of fresh leukemic progenitor cells. Nevertheless, we were able to compare the efficacy of three distinct purging protocols at a sensitivity level of 3 logs. Further improvement of the sensitivity may be achieved by defining better in vitro growth conditions for T-lineage ALL blasts.

In view of recent clinical data showing that posttransplant leukemic relapse remains a major unsolved problem in both allogeneic and autologous BMT for ALL,¹ we conclude that future autologous BMT studies in ALL should focus on designing more effective cytoreductive preparative regimens, and application of combined treatment protocols such as IT + 4-HC for more effective purging of autografts should be considered. A clinical phase I trial would be required to verify the repopulation capacity of autografts purged ex vivo with IT + 4-HC, since the toxicity to repopulating pluripotent human bone marrow stem cells cannot be measured by currently available in vitro cell culture techniques.

ANNOUNCEMENTS

INTERNATIONAL SOCIETY OF HEMATOLOGY (ISHPAD) VI INTERNATIONAL CONGRESS OF THE ASIA-PACIFIC DIVISION

**December 7-10, 1987
Bombay, India**

The Organizing Committee of the VI Congress has assigned Mr. Aloke C. Bagchi to function as the Official Liaison and Program Coordinator for the United States and Canada for the promotion and dissemination of Congress information and the handling of all special travel programs for the delegates and their spouses from North America.

All ASH members are welcome to contact Mr. Bagchi at 6101 N Talman Ave, Chicago, IL 60659-0557, telephone (312) 465-8337, for the Congress brochure, registration forms, and information pertaining to the Congress and the special economy program for India and Nepal.

BAYLOR UNIVERSITY MEDICAL CENTER, DALLAS, TEXAS "ONCOLOGY PRACTICE 1987: A PERSPECTIVE" Snowmass, Colorado February 1-7, 1987

For further information, contact: Stephen E. Jones, MD, Sammons Cancer Center #4800, Baylor University Medical Center, 3500 Gaston Avenue, Dallas, TX 75246

AMERICAN BOARD OF INTERNAL MEDICINE 1987 SUBSPECIALTY EXAMINATIONS IN MEDICAL ONCOLOGY AND CRITICAL CARE MEDICINE

Registration Period: January 1, 1987 through April 1, 1987
Examination Date: November 10, 1987

For information and applications forms, please contact: Registration Section, American Board of Internal Medicine, 3624 Market Street, Philadelphia, PA 19104.

CLINICAL HEMATOLOGY AND ONCOLOGY: 1987

**February 16-18, 1987
Sponsored by Scripps Clinic and Research Foundation, San Diego, CA
Laurence Harker, MD, Program Chairman**

This conference is designed for hematologists, oncologists, internists, pediatricians, and pathologists interested in the diagnosis and management of hematologic and oncologic disorders. An outstanding faculty from across the country has been assembled to discuss various aspects of these fields, to aid clinicians in sorting out the important from the trivial, and to help identify those recent advances which will withstand the test of time. 21 hours Cat. I.

For further information and application forms, contact: Bonny Mower, Department of Academic Affairs, Box 400S, Scripps Clinic and Research Foundation, 10666 N Torrey Pines Rd, La Jolla, CA 92037. Telephone (619) 457-8556.

AMERICAN SOCIETY OF HEMATOLOGY

Spring Symposium on Hematopoietic Growth Factors

Durham, North Carolina

April 20–21, 1987

The American Society of Hematology is holding a two-day symposium on hematopoietic growth factors sponsored by Burroughs Wellcome Company, to be held at the Searle Center in Durham, North Carolina on April 20 and 21, 1987. The topics will include the molecular biology of the hematopoietic growth factors, their biological actions, and the results of in vivo studies with these molecules in experimental animals and humans. Among the participants will be Steven Clark, Malcolm Moore, David Golde, Judith Gasson, Ken Kaushansky, Gordon Wong, Peter Quesenberry, John Adamson, and Colin Sieff.

Additional information and details of the program are available through Dr Wendell F. Rosse, PO Box 3934, Duke University Medical Center, Durham, NC 27710. Individuals interested in submitting abstracts or poster presentations, or preregistering are encouraged to do so by March 1, 1987. Maximum registration: 200.

ERRATUM

In the article by Griesser et al entitled "The Structure of the T Cell Gamma Chain Gene in Lymphoproliferative Disorders and Lymphoma Cell Lines" which appeared in the August 1986 issue (Volume 68, pp 592–594), two errors were made. In the abstract, the sentence "TcR γ was rearranged in all T cell lymphomas and B cell lymphoma cell lines" should read "TcR γ was rearranged in all T cell lymphomas and in some B cell lymphomas and B cell lymphoma cell lines." The last sentence in the introduction should read: "These studies indicate that rearrangement of TcR γ occurs before TcR β and that rearrangement of the γ chain locus by itself is a poor indicator of cell lineage."

Assistant/Associate Blood Bank Medical Director

Barnes Hospital is a 1200-bed teaching hospital affiliated with Washington University Medical Center providing complete medical and surgical specialty services, active cardiac, renal, liver, and bone marrow transplantation programs as well as 6000 apheresis procedures annually. Closely integrated training affiliation with Missouri-Illinois Red Cross Regional Blood Program. The tenure track assistant or associate professor appointment involves shared teaching, investigative, and administrative responsibilities. Well-equipped research laboratory facilities provided. Interested individuals should submit resumes (including three references) to:

Hugh Chaplin, MD
Barnes Hospital Blood Bank
Box 8118
4949 Barnes Hospital Plaza
St. Louis, MO 63110

DIRECTOR OF BONE MARROW TRANSPLANT PROGRAM

TEMPLE UNIVERSITY HEALTH SCIENCES CENTER is seeking a Board Certified MD (Hematology and/or Oncology) to serve as Director of Bone Marrow Transplant Program. The position is at Associate Professor/Professor level tenure track. The position involves teaching, research and clinical care with major responsibilities for the Bone Marrow Transplantation Program. Please respond to:

Dr. R. Colman
Chief of Hematology/Oncology

For Alexander, who can't produce enough antibodies to fight infection...

Young or old, patients without sufficient levels of antibodies face overwhelming infection...and they urgently need help. Aggressive IGIV treatment with GAMIMUNE® N gives these patients the edge that may make the difference: antibodies against major bacterial, viral and fungal pathogens, in just minutes.

For patients like Alexander, GAMIMUNE® N provides premium IGIV: immune globulin that contains at least 98% pure gamma globulin¹; unmodified "native" IgG with immunologic activity of normal plasma; and documented *in vitro* inactivation of HTLV-III virus* during fractionation from plasma to final gamma globulin.²

When patients don't have enough antibodies to fight infection, like Alexander, it's nice to know that GAMIMUNE® N does.

Aggressive IGIV treatment in immunodeficiency syndromes. Also for both chronic and acute ITP in children and adults.

GAMIMUNE® N
Immune Globulin
Intravenous (Human) 5%
(in 10% Maltose), pH 4.25

No *more* expensive than other IGIV therapy, GAMIMUNE® N may, in some cases, be *less* expensive. A contributing factor is that GAMIMUNE® N is a convenient, ready-to-use, liquid formulation that saves valuable pharmacy time.

No premium cost
for TODAY'S
IGIV.

*The Cohn-Oncley process used to produce Gamimune®N has been challenged *in vitro* with a virus spike of 1×10^5 TCID (Tissue Culture Infectious Doses) of HTLV-III and found to remove and/or inactivate the viral challenge. In addition, Gamimune®N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 TCID (Tissue Culture Infectious Doses) reduction of HTLV-III.²

Please see following page for brief summary of prescribing information

GAMIMUNE[®] N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune[®] N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune[®] N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The *in vivo* half-life of Gamimune[®] N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood, there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N is 16.5 mEq/L (~0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune[®] N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune[®] N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune[®] N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune[®] N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune[®] N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune[®] N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune[®] N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune[®] N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune[®] N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune[®] N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune[®] N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune[®] N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune[®] N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PL^{A1} alloimmune antibody with platelet anti PL^{A1} specificity) also responded to treatment with Gamimune[®] N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N should be considered, in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune[®] N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune[®] N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune[®] N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune[®] N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune[®] N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune[®] N may be diluted with 5% dextrose in water (D5W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune[®] N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune[®] N. It is not known whether Gamimune[®] N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune[®] N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune[®] N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune[®] N. Symptoms reported with Gamimune[®] N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune[®] N at the infusion site was reported in some cases.

In further studies of Gamimune[®] N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune[®] N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune[®] N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune[®] N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune[®] N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune[®] N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune[®] N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune[®] N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune[®] N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune[®] N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes, if well tolerated, the rate may be gradually increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Journal orders must be paid in advance.

Individual journal orders must be paid by
personal check or credit card.

This new journal provides an international forum for the publication of timely review articles on the most important clinical and research topics in transfusion medicine. The scope of the journal covers all basic science and practical aspects in the field.

Invited articles, written by acknowledged authorities, will discuss concepts of immunology, protein chemistry, genetics, molecular and cellular biology, microbiology, immunohematology, blood banking, clinical laboratory developments, and other important issues.

Interested contributors should submit an outline of their proposed articles and a tentative submission date to:

McMaster University Medical Centre

1200 Main Street West

Hamilton, Ontario, Canada L8N 3Z5

Transfusion Medicine Reviews will be an authoritative journal for hematologists, technologists, nurses, and other scientific personnel involved in the provision of blood products. Medical students, residents, and fellows interested in transfusion medicine will find this a primary source of information for important issues in the field.

Scheduled topics for Vol. 1, 1987:

- Post transfusion non-A, non-B, hepatitis. *Harvey J. Alter*
- The association of blood group antigens with red cell membrane glycoproteins. *David J. Anstee*
- The effects of red cell antigens and blood transfusion on renal transplantation. *Morris A. Blajchman*
- The role of the hematocrit in bleeding. *Bernard Boneu (with F. Fernandez)*
- Complications associated with apheresis procedures. *Marc Boogaerts*
- Controversies in the use of Rh immunoglobulin in the prevention of Rh alloimmunization. *J.M. Bowman*
- The significance of complement on the red cell surface. *John J. Freedman*
- The significance of IgG on the red cell surface. *George Garratty*
- The role of platelet glycoproteins in platelet function. *James N. George*
- Putative mechanisms of the Factor VIII bypass activity of Factor IX concentrates. *Alan Giles*
- Transfusion associated AIDS. *Jerome E. Groopman*
- The Factor VIII molecule-new perspectives. *Leon W. Hoyer*
- The use of intravenous IgG in the treatment of immune disorders. *John Kelton*
- The significance of reticuloendothelial function in the immune destruction of blood cells. *John Kelton*
- Immunogenicity of platelet membrane glycoproteins. *Tom Kunicki*
- Treatment of patients with Factor VIII antibodies. *Jeanne M. Lusher*
- Recent Developments in the Kell blood group system. *W. Laurence Marsh*
- White cell antigens and antibodies. *J. Jeffrey McCullough*
- The similarities amongst the factors affecting the successful storage of platelets and red cells. *Scott Murphy*
- ABO and Lewis antigens in tissues. *Raphael Oriol*
- The immunohematological complications of bone marrow transplantation. *Lawrence D. Petz*
- The use of blood products for the support of bone marrow transplant recipients. *Sherrill J. Slichter*

Advances in Haematology 1987

19th Annual Course

15-19 June 1987

This is a five-day course for specialists and trainees in haematology, with emphasis on progress in the fundamental basis of blood disorders, their diagnosis and their treatment.

Topics will include: New monoclonal antibodies and clusters of differentiation; The MIC classification of acute leukaemias; Management of sickle cell disease; Iron metabolism; Use of blood products; Developments in blood counting; Bone marrow transplant (allogeneic and autografts); Gene probes as diagnostic tools; Alpha-interferon and deoxycytosine for chronic leukaemias; Platelet function and abnormalities; Megaloblastic anaemias revisited; Classification of lymphomas.

There will be lectures, clinical case presentations, and diagnostic slide sessions. Speakers will be members of the Department of Haematology and the MRC Leukaemia Unit (D. Catovsky, D.A.G. Galton, J.M. Goldman, J. Hows, S.M. Lewis and L. Luzzatto) as well as eminent guest lecturers, which this year will include Dr. Elaine S. Jaffe, Chief, Hematopathology Section, National Cancer Institute, U.S.A.

Course Organisers: Drs. S.M. Lewis and D. Catovsky

Course fee (including catering): £205

Application forms from: School Office (SSC), Royal Postgraduate Medical School, Hammersmith Hospital, Du Cane Road, London W12 0HS, Tel: 01 740 3118.

Two academic positions available for a Clinical Immunologist and Hematologist/Oncologist with experience in Bone Marrow Transplantation. A splendid 14 bed marrow transplantation facility, animal research laboratories, clinical immunology laboratories and equipped research laboratories are available. Level of appointment and academic rank dependent upon experience and prior academic record.

All inquiries should be directed to
Robert A. Good, M.D., Ph.D.

Hematologist/or Internist (Half time)

St. Luke's/Roosevelt Hospital Center, a 1,315 bed University hospital affiliated with Columbia University College of Physicians and Surgeons, and a provider of healthcare to over 400,000 people living in Manhattan's Upper West Side, is seeking a half-time physician in its Comprehensive Sickle Cell Clinic, as well as medical backup in the ER and inpatient units. Days and hours are somewhat flexible. Interested candidates are invited to submit curriculum vitae to:

Cheryl Hunter-Grant, Program Coordinator
Comprehensive Sickle Cell Center
St. Luke's/Roosevelt Hospital Center
114th at Amsterdam Avenue

ANNOUNCEMENT

FIRST INTERNATIONAL SYMPOSIUM ON INHIBITORY FACTORS IN THE REGULATION OF HEMATOPOIESIS APRIL 26-28, 1987 INSTITUT PASTEUR, PARIS, FRANCE

Guest speakers:

A. AXELRAD (Canada)	B.I. LORD (U.K.)
H. BROXMEYER (USA)	D. METCALF (Australia)
E. FRINDEL (France)	T. OLOFSSON (Sweden)
O.D. LAERUM (Norway)	W.R. PAUKOVITS (Austria)
	W. VAINCHENKER (France)

This symposium is held under the auspices of "L'Institut National pour la Recherche et la Santé Médicale" and "l'Association pour la Recherche sur le Cancer" and is organized by Pr. A. NAJMAN (Faculté de Médecine St. Antoine, Paris), Dr. M. GUIGON (Institut Gustave Roussy, Villejuif, France), Pr. N.C. GORIN (Faculté de Médecine St. Antoine, Paris) and Dr. G.I. MARI (Inserm V263 University, Paris 7). Preregistration is required. For information please contact the Secretariat, Département d'Hématologie, Faculté de Médecine Saint Antoine, 27 rue de Chaligny, 75012 Paris, France.

AMGEN BIOLOGICALS INTRODUCES – Granulocyte Colony Stimulating Factor

For scientists investigating the development and function of the immune system and related disorders, Amgen Biologicals offers a new white blood cell growth factor: purified, human recombinant G-CSF for *in vitro* and laboratory animal use only.

Recent advances in genetic engineering have permitted Amgen scientists and collaborators to pioneer the cloning of one of the human CSFs, granulocyte colony stimulating factor (G-CSF). This factor preferentially stimulates the development of granulocyte precursors in the bone marrow. It further mediates specific immune defense responses of mature granulocytes targeted against invading microorganisms. G-CSF has been shown to induce some myeloid leukemia cells to differentiate from their immature cancerous state to mature cells with apparently normal characteristics. *In vitro*, G-CSF has demonstrated its ability to support granulocyte/macrophage colony formation (CFU-GM), with a predominance of neutrophil colonies.

PURITY: > 95% prior to formulation in HSA
ACTIVITY: ~ 1×10^8 U/mg CSF
STABILITY: > 4 months

For more information and ordering call:

Toll Free: 800-343-7475

In California: 805-499-5725

Amgen Biologicals / 1900 Oak Terrace Lane / Thousand Oaks, CA 91320

CAUTION: For research use only in laboratory animals or *in vitro* testing. Not for diagnostic or human

BRAVO!

Introducing the Versatile Performer New COAG-A-MATE[®] XC

The new COAG-A-MATE XC delivers the versatile, reliable performance essential for today's coagulation testing needs.

- **Performance that's practical** — Does all key coagulation tests: PT, APTT, TT (thrombin time), fibrinogen and factor assays. Automated performance for rapid throughput.
- **Performance you can applaud** — Advanced programming allows all testing parameters to be temporarily or permanently modified by operator, with results expressed in %, ratio, seconds or mg/dl. Holds up to 15 standard curves in permanent memory.
- **Performance you can afford** — Equipped with numerous labor- and time-saving features, like semiautomated pump calibration

and rapid priming/depriming, COAG-A-MATE XC is economical to operate and attractively priced for today's mid-sized laboratory.

- **Performance you can depend on** — Two separate self-checking diagnostic programs help ensure reliable performance and trouble-free operations.

Consider: Thousands of

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

Burroughs Wellcome Co.
3030 Cornwallis Road
Research Triangle Park, NC 27709

Patients Rescued

WELLCOVORIN[®] TABLETS (leucovorin calcium)

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.¹

¹Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

WELLCOVORIN® TABLETS (leucovorin calcium)

Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B₁₂. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below 5×10^{-8} M.^{1,2} The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.^{3,4,5}

You can help us raise the colorectal cancer cure rate.

"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkup Guidelines for men and women over 50 without symptoms:

- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces
cancer alone.

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

THE
T-CELL
PUZZLE

ARE YOU MISSING THE VITAL PIECES?

Coulter Immunology can help you solve the puzzle. With the broadest line of monoclonal antibodies, Coulter Immunology provides the tools to solve the puzzle of immune-related disorders. We bring you vital pieces like 2H4 and 4B4, for which there are no equivalents. The inducer of help (T4+4B4+) and inducer of suppression (T4+2H4+) are functionally unique subsets of the T4 helper cells. These are available in fluorescein and phycoerythrin derivative conjugates for multiple color analysis. Ask us for references on these unique antibodies that are being used to characterize disease states, such as SLE, MS, rheumatoid arthritis, and AIDS. Our broad line includes monoclonals for both T and B lymphocytes, monocytes, natural killer cells, specific activation markers, isotypic controls, and support products. We have the pieces you're looking for today. Call us at 1-800-327-3778 or 1-800-432-6518, Ext. 6880 from Florida. Look for our new COULTER CLONE® monoclonal antibodies to B cell activation antigens coming soon.

©1986 COULTER CORPORATION

COULTER IMMUNOLOGY

Today's IGV. Don't settle for less.

For immunodeficiency syndromes: aggressive protection against infection

Patients without sufficient levels of antibodies face overwhelming infection, and they need help. Infusion with GAMIMUNE® N gives these patients the edge that may make the difference: antibodies against major bacterial, viral and fungal pathogens... in just minutes.

For both chronic and acute ITP in children and adults: rapid elevation of platelet levels

GAMIMUNE® N may initiate a therapeutic increase in platelets in both children and adults with idiopathic thrombocytopenic purpura (ITP).^{1*} Treatment with GAMIMUNE® N has enabled some ITP patients to undergo major surgery.¹

IGIV that's at least 98% pure gamma globulin

Cutter's fractionation method (Cohn-Oncley 6 & 9) contains all the necessary steps to produce high purity immune globulin. GAMIMUNE® N contains no foreign contaminants, no detectable levels of protein aggregates or vasoactive enzymes.² With GAMIMUNE® N you get what you expect... IGV containing at least 98% pure gamma globulin.¹

GAMIMUNE® N
Immune Globulin
Intravenous (Human) 5%
(in 10% Maltose), pH 4.25

Documented in vitro inactivation of HTLV-III virus[†]

[†]The Cohn-Oncley process used to produce Gamimune®N has been challenged *in vitro* with a virus spike of 1×10^5 TCID (Tissue Culture Infectious Doses) of HTLV-III and found to remove and/or inactivate the viral challenge. In addition, Gamimune®N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 TCID (Tissue Culture Infectious Doses) reduction of HTLV-III.[‡]

"Native" IGIV

GAMIMUNE®N is manufactured without chemical modification. This means GAMIMUNE®N antibodies maintain normal opsonization capacity, have a normal distribution of IgG subgroups and provide the immunologic activity of normal plasma.¹

Artist's interpretation of HTLV-III virus.

Today's simple, economical IGIV: the only ready-to-use liquid

Dose for dose, GAMIMUNE®N saves money by eliminating valuable reconstitution time in the pharmacy. Gram for gram of protein, GAMIMUNE®N is affordable; there is no premium price for TODAY'S IGIV.

Artist's interpretation of blood platelets.

*It is not possible to predict which patients with ITP will respond to therapy.

¹In patients who respond to therapy, a rise in platelet count is generally rapid (within 1 to 5 days), transient (most often lasting from several days to several weeks) and should not be considered curative.

From the original IGIV, today's IGIV...it offers more

Please see following page for brief summary of prescribing information.

GAMIMUNE[®] N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gammimune[®] N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gammimune[®] N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The *in vivo* half-life of Gammimune[®] N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood, there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gammimune[®] N is 16.5 mEq/L (~0.3 mEq/g protein), a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gammimune[®] N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gammimune[®] N at a dose of 150 mg/kg body weight, following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gammimune[®] N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gammimune[®] N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gammimune[®] N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gammimune[®] N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gammimune[®] N may initiate a therapeutic increase in the platelet count. In clinical studies of Gammimune[®] N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gammimune[®] N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gammimune[®] N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gammimune[®] N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gammimune[®] N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gammimune[®] N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PLA² alloimmune antibody with platelet anti PLA¹ specificity) also responded to treatment with Gammimune[®] N, at a dose of 400 mg/kg body weight daily for 5 days, there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gammimune[®] N should be considered, in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gammimune[®] N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gammimune[®] N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gammimune[®] N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gammimune[®] N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gammimune[®] N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gammimune[®] N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gammimune[®] N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gammimune[®] N. It is not known whether Gammimune[®] N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gammimune[®] N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gammimune[®] N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gammimune[®] N. Symptoms reported with Gammimune[®] N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gammimune[®] N at the infusion site was reported in some cases.

In further studies of Gammimune[®] N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gammimune[®] N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gammimune[®] N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gammimune[®] N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gammimune[®] N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gammimune[®] N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gammimune[®] N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gammimune[®] N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gammimune[®] N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gammimune[®] N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes, if well tolerated, the rate may be gradually increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

TIMES CHANGE.

MEET YOUR NEWEST BLOOD BANKER.

THE OLYMPUS PK7100 FULLY AUTOMATED PRETRANSFUSION BLOOD TESTING SYSTEM

Today, with the increased demand in blood testing for transfusion purposes, blood bankers suddenly need new help.

The Olympus PK7100 is the solution. It automatically performs simultaneous routine blood typing (ABO and RH), freeing experienced blood bankers to perform additional tests for the increased incidence of infectious agents (Hepatitis, HTLV-III, etc.).

The PK7100 analyzes up to 240 samples/hour, and features the revolutionary and patented Olympus "Terraced" Microtiter Plate, which reduces reagent consumption and holds cells more firmly in place during less delicate handling. And while the high discrimination PK7100 takes multiple readings

on the terraces for extremely accurate automated readings, the terraced plate design provides more stable agglutination/non-agglutination patterns for easy visual confirmation.

And the PK7100 is backed with Olympus' complete support package and extensive field service network.

Other PK7100 features include:

- Full data processing capability: Convenient computerized data storage; Video monitor; High speed printer; RS-232C interface; Triple-check system of bar code labels.
- Micro-syringes (for precision dispensing of serum, blood cells, diluent and reagents).
- Virtually no disposables/consumables.
- Advanced compact design (for easy placement, easy access, and efficient workstation operation).

For further information call TOLL FREE 800-223-0125 or 800-626-0236 (in NY).

"Terraced" Microtiter Plate

OLYMPUS

Olympus Corporation, Clinical Instruments Division

1987 Helena Hemostasis Advanced Wet Workshops

What Is It?

A series of comprehensive, advanced, one day Hemostasis Wet Workshops presented by Helena Laboratories. The session will include lectures on the PFI (Proenzyme Functional Inhibitor) Index, platelet aggregation and chromogenic substrates as well as hands-on training with AT-III. Workshop participants will perform the COATEST® Antithrombin Chromogenic Assay using Microtiter plates. This procedure is just one demonstration of cost reduction with advanced technology for your lab.

Why Should I Attend?

These key topics will be covered.

Chromogenic Substrates —

We will discuss the clinical applications of chromogenic substrates. As chromogenic substrate research progresses new products become available for the clinical lab. These new substrates allow the coagulation laboratory to perform sensitive, specific assays for various components of the hemostatic system.

AT-III Microplate Procedures —

Hands-on training with AT-III, levels can be measured easily with the COATEST Antithrombin Kit. The kit utilizes chromogenic substrate methodology to detect the conversion of pNA by thrombin spectrophotometrically. For greater efficiency, it can be automated on most centrifugal analyzers or run in microtiter plates.

NEW

PFI Index — A lecture and slide series on a new diagnostic tool for management of intensive care patients. The use of the Proenzyme Functional Inhibitor (PFI) Index allows the clinician to identify high-risk patients, obtain

When and Where?

1987 Advanced Hemostasis Spring Workshop Schedule

prognostic information, and judge therapeutic effectiveness.

NEW

COA-SET Assays — KabiVitrum chromogenic substrates contribute greatly to the investigation of coagulation and fibrinolysis. Two new assays, COA-SET t-PA/t-PA Inhibitor and COA-SET Protein C will be discussed.

Platelet Aggregation — See the only aggregometer with a 4 color printer, making interpretation simple. Helena's Monitor IV PLUS Platelet Aggregation Recorder, features the ease and accuracy of automated 4 channel aggregation, and a 7 inch CRT for data entry display and preview.

NEW

Helena "Q.I.C." Bleeding Time Device — We'll introduce a new bleeding time procedure and discuss the diagnostic value of bleeding time testing for platelet defects and some vascular disorders.

Guest Speaker — A representative from KabiVitrum in Sweden will be joining us again this year in our presentation of the Advanced Hemostasis Wet Workshops. This will be an excellent opportunity for you to meet and talk with one of the scientists who formulate and stand behind the innovative technology of chromogenic substrates.

How Do I Get More Information?

All laboratory professionals (managers, supervisors, technologists, pathologists, hemotologists and coagulation researchers) are welcome. For more information call our Workshop Registrar toll free 800-231-5663. In Texas, 800-392-3126.

MALPRACTICE:

A GUIDE TO AVOIDANCE AND TREATMENT

Kenneth E. Brooten, Jr., Esquire
and **Stuart Chapman**

This new text provides practical, in depth coverage about the avoidance and treatment of healthcare malpractice.

The book presents practical, daily methods about how to avoid malpractice as well as pre and post trial procedures. Helpful guidelines on avoiding risks in the hospital, the do's and don't's of prescribing, how to discharge patients, and the establishment of effective patient relationships, will aid the practitioner in the prevention of potential suits. Chapters describing the service of the summons, attorney selection, the anatomy of a trial, and case settlement, help to familiarize the healthcare professional with each stage of a lawsuit. Malpractice checklists and forms add to the text's practical value.

Physicians, osteopaths, nurses, chiropractors, psychologists, and other health care providers, will find **Malpractice: A Guide to Avoidance and Treatment**, an indispensable, ready reference.

CONTENTS: Introduction. Acknowledgements. Dedications. Malpractice What Is It? Vicarious Liability. Establishing Effective Patient Relationships. The Role of the Consultant. The Do's and Don't's of Prescribing. Avoiding Risks in the Hospital. The Medical Record. How to Discharge a Patient. Service of Summons. Selecting Your Defense Attorney. The Plaintiff's Attorney. Pre-Trial Procedures. The Expert Witness. The Anatomy of a Trial. When to Settle a Case. Post Trial-After The War is Over. Malpractice 2000.

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to *BLOOD*. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: *BLOOD* will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the *BLOOD* Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared

in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in *BLOOD* represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a \$50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to: John W. Adamson, MD, Editor

BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to *BLOOD* and subsequently accepted for publication will be assessed a \$50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of *BLOOD* will assume that the authors of research papers published in *BLOOD* are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and two complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least ⅛ inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus*. (A "List of Journals Indexed in Index Medicus" —with abbreviations— is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

To understand much of what we're doing with respect to cancer research, you'd need a graduate degree in microbiology or biochemistry.

But to understand how well our educational programs and service resources help both patients and their families, simply talk to one out of every 100 Americans who are part of our volunteer program. Or talk to one of the 3 million who've survived cancer.

The battle isn't over but we are winning.

Please support the American Cancer Society.

Blenoxane[®] (sterile bleomycin sulfate)

Brief Summary of Prescribing Information (1) 10 84 For complete prescribing information please consult product literature

WARNING

It is recommended that Blenoxane[®] be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma — Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas — Hodgkin's, reticulum cell sarcoma, lymphosarcoma

Testicular Carcinoma — Embryonal cell, choriocarcinoma, and teratocarcinoma

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary — This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{CO}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{CO} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{CO} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

- (1) Maintain FiO_2 at concentrations approximately that of room air (25%) during surgery and the post-operative period.
- (2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions — In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes — These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other — Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinoma treated with a combination of Blenoxane and Velban[®]. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

New in 1987!

TRANSFUSION MEDICINE REVIEWS

Editor-in-Chief

Morris A. Blajchman, M.D., F.R.C.P. (C)

Volume 1, 1987 (First issue, March)

Published 3 times in 1987, subsequently,

quarterly, approx. 216 pages in 1987,

approx. 288 pages in subsequent years

Annual subscription rate, U.S.A. and Canada:

\$39.00 individuals/\$51.00 institutions

(All other countries: \$56.00)

ISSN: 0887-7963

Journal orders must be paid in advance.

Individual journal orders must be paid by
personal check or credit card.

This new journal provides an international forum for the publication of timely review articles on the most important clinical and research topics in transfusion medicine. The scope of the journal covers all basic science and practical aspects in the field.

Invited articles, written by acknowledged authorities, will discuss concepts of immunology, protein chemistry, genetics, molecular and cellular biology, microbiology, immunohematology, blood banking, clinical laboratory developments, and other important issues.

Interested contributors should submit an outline of their proposed articles and a tentative submission date to:

Dr. Morris A. Blajchman, Editor-in-Chief

Transfusion Medicine Reviews

Department of Pathology

McMaster University Medical Centre

1200 Main Street West

Hamilton, Ontario, Canada L8N 3Z5

Transfusion Medicine Reviews will be an authoritative journal for hematologists, technologists, nurses, and other scientific personnel involved in the provision of blood products. Medical students, residents, and fellows interested in transfusion medicine will find this a primary source of information for important issues in the field.

Scheduled topics for Vol. 1, 1987:

- Post transfusion non-A, non-B, hepatitis. *Harvey J. Alter*
- The association of blood group antigens with red cell membrane glycoproteins. *David J. Anstee*
- The effects of red cell antigens and blood transfusion on renal transplantation. *Morris A. Blajchman*
- The role of the hematocrit in bleeding. *Bernard Boneu (with F. Fernandez)*
- Complications associated with apheresis procedures. *Marc Boogaerts*
- Controversies in the use of Rh immunoglobulin in the prevention of Rh alloimmunization. *J.M. Bowman*
- The significance of complement on the red cell surface. *John J. Freedman*
- The significance of IgG on the red cell surface. *George Garratty*
- The role of platelet glycoproteins in platelet function. *James N. George*
- Putative mechanisms of the Factor VIII bypass activity of Factor IX concentrates. *Alan Giles*
- Transfusion associated AIDS. *Jerome E. Groopman*
- The Factor VIII molecule-new perspectives. *Leon W. Hoyer*
- The use of intravenous IgG in the treatment of immune disorders. *John Kelton*
- The significance of reticuloendothelial function in the immune destruction of blood cells. *John Kelton*
- Immunogenicity of platelet membrane glycoproteins. *Tom Kunicki*
- Treatment of patients with Factor VIII antibodies. *Jeanne M. Lusher*
- Recent Developments in the Kell blood group system. *W. Laurence Marsh*
- White cell antigens and antibodies. *J. Jeffrey McCullough*
- The similarities amongst the factors affecting the successful storage of platelets and red cells. *Scott Murphy*
- ABO and Lewis antigens in tissues. *Raphael Oriol*
- The immunohematological complications of bone marrow transplantation. *Lawrence D. Petz*
- The use of blood products for the support of bone marrow transplant recipients. *Sherrill J. Slichter*

NOW YOU CAN SEPARATE THE BEST FROM THE REST

...WITH THE CUTTER NEOCEL™ SYSTEM FOR YOUNG RED CELLS.

Now, young red cells can be routinely used to improve the management of chronically transfused patients by decreasing the transfusion requirement and the rate of iron loading... or whenever the best red cell product is indicated. Because now there's a commercially available blood bag system for efficient, reliable separation of red cells by age.

A BETTER RED CELL PRODUCT
The Neocel System delivers a product rich in neocytes (young red cells) with a 31% extension in mean half-life over normal packed red cells.

Color enhanced red cells 4400 $\times$. Top: least dense (youngest) fraction. Bottom: most dense (oldest) fraction.

SIMPLE, FAST PROCEDURE

Neocel provides a simple method of separation using a standard centrifuge, significantly reducing cost and technical difficulty compared to present methods.

Provide a better red cell product, with the Neocel System for Young Red Cells...another Component Enhancement Product, only from Cutter.

REVIEW

The Kinetics of Immune Reconstitution After Human Marrow Transplantation

By Lawrence G. Lum

Human marrow transplantation for the treatment of malignant and nonmalignant disorders is becoming an established modality of therapy. As in any aggressive therapeutic modality, the benefits must be balanced with the risks of the therapy. The aggressive chemoradiotherapy used to prepare patients for marrow transplantation creates a transient immunodeficiency disorder postgrafting until the transferred donor marrow reestablishes a competent immune system. Immune reconstitution posttransplant follows a general pattern developing from immature to mature immune functions. Immune reactivity during the first month postgrafting is extremely low. Cytotoxic and phagocytic functions recover by day 100, while more

specialized and cooperative functions of T and B cells remain impaired up to one year or more postgrafting. After the first year postgrafting, the various components of the immune systems of most healthy marrow recipients begin to work synchronously, whereas the immune systems of recipients with chronic graft-v-host disease (GVHD) remain crippled. Recent evidence shows that transfer of specific immunity from marrow donors to marrow recipients plays a role in reestablishing immunocompetence. Transferred antigen-specific immunity may explain why more recipients do not die from overwhelming infections.
© 1987 by Grune & Stratton, Inc.

BONE MARROW transplantation is an accepted mode of therapy for immunodeficiency disorders, aplastic anemia, or hematologic malignancies.¹⁻² The chemoradiotherapy used to prepare marrow graft recipients ablates existing normal and abnormal immunohematopoietic marrow elements, provides immunosuppression to permit engraftment, and creates space in the marrow microenvironment for the donor marrow to develop. Although the immunodeficiency is created under carefully controlled circumstances, the marrow graft recipients are extremely susceptible to life-threatening infections with a variety of bacterial, viral, and fungal pathogens.³⁻⁶ The first 100 days postgrafting is the interval of maximum risk; however, marrow graft recipients with chronic graft-v-host disease (GVHD) continue to be at risk for bacterial, viral, and, less frequently, fungal infections.

Marrow transplantation offers a model of iatrogenic immunodeficiency that is unique in that immunity generally recovers if the transplant recipient does not succumb to transplant related complications or recurrent disease. This model permits dissection of the various elements of the human immune system as they reappear under the influence of various treatment modalities postgrafting. An understanding of the kinetics of immune reconstitution in the marrow transplant model will enhance our understanding of immunodeficiency disorders. Parallels can be drawn between the transplant model and the defects seen in immunodeficiency disorders and the regressing immune systems of patients with acquired immunodeficiency syndrome (AIDS).

The various in vivo and in vitro immune function tests of the marrow recipients will be discussed in terms of the first 100 days (short-term recipients) and from 100 days to years (long-term recipients) postgrafting. The areas that will be

reviewed include: (1) general considerations of immunity, (2) issues related to acute GVHD in short-term recipients, (3) issues related to chronic GVHD in long-term recipients, (4) mucosal defense system, (5) recovery of granulocyte and accessory cell functions, (6) recovery of cytotoxic functions of lymphocytes, (7) T cell-mediated immunity early postgrafting, (8) T cell-mediated immunity in long-term recipients, (9) B cell-mediated immunity early postgrafting, (10) B cell-mediated immunity in long-term recipients, (11) use of immunomodulators to accelerate immune reconstitution, (12) reimmunizations for marrow recipients, (13) recapitulation of ontogeny, and (14) future directions.

GENERAL CONSIDERATIONS OF IMMUNITY

Studies at a number of transplant centers have shown that the repopulation of the immune and hematopoietic systems is dependent on appropriate proliferation, maturation, and differentiation of donor cells. The signals that direct immune

reconstitution are largely unknown. However, the key factor in immune reconstruction is time after grafting.⁷⁻¹³ Successful immune reconstruction is dependent on the orchestrated emergence of many different components of the immune system. All marrow graft recipients have a profound impairment of most immune functions during the first four to five months postgrafting, regardless of the type of graft (autologous, syngeneic, or allogeneic), the type of underlying disease, the conditioning regimen, the type of postgrafting immunosuppression, the preparative regimen, or the presence of acute GVHD.⁷⁻¹⁶ Immune reconstitution in most healthy long-term survivors is successfully completed by one to two years postgrafting, whereas the same process in recipients with chronic GVHD is delayed, leaving them susceptible to infections.

The marrow recipient progresses from an immunologic state characterized by primitive cytotoxic systems such as natural killer activity, and the predominance of cells with suppressive functions to a more mature immunologic state characterized by finely tuned immune responses. Initially there is reestablishment of phagocytic functions followed by repopulation of the early lymphoid elements responsible first for primitive and then for more specific cytotoxic functions. Subsequently T cells responsible for regulatory functions emerge. The early suppressive T cell signals are followed by the development of mature helper T cell signals. Evidence suggests that the transition from a predominance of suppression to a predominance of helper activity in the recipient can be disrupted by chronic GVHD or its treatment. Transfer of existing donor immunity may play a role in achieving antigen-specific immune reconstitution in both the T and B cell compartments of the recipient immune system.

The role of the host thymus in this reconstitution process remains elusive in human marrow transplantation. Age of recipient at transplant, irradiation, and chemotherapy could all affect the functional capacity of the thymic microenvironment to properly facilitate the maturation of donor T cells. Furthermore, other nonthymic components of the immune system that may play roles in controlling the recapitulation of immune ontogeny could also have been damaged during the preparative regimen. Though ill defined, both thymic and nonthymic factors influence immune reconstitution.

Although host immunity is severely compromised by the preparative regimens, it is not absent. Graft rejections or lack of sustained engraftment in patients with severe aplastic anemia or patients who receive T cell-depleted marrow are probably mediated by persistent host immunity. Pretransplant transfusion sensitization increases graft rejections in patients with aplastic anemia,¹⁶ whereas untransfused aplastic anemia patients have a lower incidence of graft rejection than their transfused counterparts.¹⁷

Graft failures in recipients who receive T cell-depleted bone marrows to prevent acute GVHD suggest that removal of all T cells may be a two-edged sword. Vigorous removal of T cells has decreased the incidence of acute GVHD but has increased the incidence of graft failure and recurrent leukemia. Graft failure occurs presumably due to residual irradiation-resistant host cells that destroy the marrow graft. (The role of cytotoxic T cells in GVHD and host defense is

reviewed on later pages.¹⁸) The general consensus is that certain T cell populations in the marrow inoculum may be needed to facilitate sustained engraftment in the face of host resistance and to maintain immune surveillance against the expansion of residual leukemic clones.

Low levels of persistent host immunity may play a protective role against bacterial, fungal, and viral pathogens in the first three months after marrow grafting. Persistent host-type isohemagglutinins can be detected up to three to four months postgrafting in recipients who receive ABO incompatible marrows.¹³ These findings suggest that surviving chemoradioresistant host lymphocytes or persistent antigen may have a role in the education of naive donor cells.

ISSUES RELATED TO ACUTE GVHD IN SHORT-TERM RECIPIENTS

When the emerging immune system in the recipient does not recognize antigens on host tissues as self, it may mount an appropriate immunologic reaction against foreign antigens (acute GVHD). This ability to attack host tissues demonstrates "misdirected" immunocompetence of the graft. This misdirected immunocompetence may be due to improper thymic reeducation, altered thymic microenvironment, or host-recipient histoincompatibility. Unfortunately, this attack often has very serious effects on the marrow recipient. The principal target organs of acute GVHD in animals and man are the skin, liver, and gastrointestinal (GI) tract.^{1,19-21} Cytotoxic cells are thought to play a major role in the immunologic attack. The clinical manifestations of acute GVHD range from mild skin rashes, impairment of liver function, and GI disturbances such as nausea, vomiting, and diarrhea to severe disease with full thickness skin eruptions with bullae formation, liver failure, bloody diarrhea from denuded intestinal epithelium, and depressed immune functions leading to life-threatening sepsis. Roughly half the marrow recipients transplanted with allogeneic bone marrow from HLA-identical siblings develop acute GVHD. Approximately 10% to 15% of all marrow recipients die of acute GVHD or its associated complications. Acute GVHD, *per se*, results in immunosuppression.

Acute GVHD may be enhanced by the presence of enterobacteria in the gut. The enterobacteria invading the gut mucosa may share antigenic determinants with host epithelium resulting in enhanced cytotoxic immune responses directed at the mucosal lining.²² Observations that support this hypothesis are (1) recipients with acute GVHD have more infections than those without GVHD^{2,23}; and (2) the protective environments of laminar air flow rooms reduce the number of infections and delay the onset of acute GVHD in recipients transplanted for aplastic anemia.²⁴

Since acute GVHD is a major impediment to successful marrow transplantation, immunosuppressive agents have been given pre- or postgrafting to prevent the development of acute GVHD.²³ These agents may further immunosuppress the recipient's immune system and prolong the susceptibility to infections. Methotrexate, cyclophosphamide, and cyclosporine (Cs) have been commonly used to prevent GVHD in man.^{23,25-27} The advantage of Cs over methotrexate is faster

engraftment, less mucositis, decreased platelet support, and a shorter hospital stay. However, immune function tests in those who received Cs prophylaxis for GVHD were not different from those who received methotrexate.²⁸ The recent combination of methotrexate and Cs to prevent GVHD has been more successful than methotrexate alone in reducing the incidence of acute GVHD and in improving long-term survival.²⁹

Adapting the well-characterized murine transplant models using T cell depletion for preventing GVHD in man has been cumbersome at best. Since cytotoxic T cells are thought to mediate the damage to tissues in acute GVHD, methods to remove T cells from marrow inocula have been used to prevent GVHD. These methods include treatment with antithymocyte globulin, monoclonal antibodies (MoAbs) directed at T cells, lectin agglutinin sedimentation, or sheep erythrocyte rosetting.³⁰⁻³⁵ Although T cell depletion procedures have decreased the incidence and severity of acute GVHD, the general consensus is that over-zealous T cell depletion has led to graft failure in recipients transplanted for acute leukemias. Furthermore, vigorous T cell depletion may be removing T cells that mediate a graft-v-leukemia effect. Most transplant groups agree that the incidence of leukemic relapse has increased with T cell depletion of the marrow graft. These procedures may also lead to increased abnormalities of immune reconstitution.

Recent studies show that depleting CD4 cells from the marrow may prevent acute GVHD and still permit sustained engraftment.³⁶ Although most models implicate cytotoxic CD8 cells in the pathogenesis of GVHD, there is no evidence that rules out the participation of CD4 cells or both CD4 and CD8 cells in the pathogenesis of acute GVHD. Follow-up studies on recipients who receive T cell-depleted marrow grafts will help sort out such issues.

No data directly support the hypothesis that specific cytotoxic cells or specific antibodies mediate the immune reaction seen in clinical GVHD.^{2,37,38} Incriminating immunologic evidence for the existence of specific alloreactive T cells or specific antibodies directed at tissues bearing non-HLA antigens is absent.^{38,39} Mixed lymphocyte culture assays using donor-derived cells from marrow recipients with acute GVHD failed to detect proliferative responses to cryopreserved host lymphocytes.⁴⁰ One recent study showed that T cell clones isolated from skin biopsies involved in acute GVHD could proliferate in response to host lymphocytes; however, direct cytotoxicity mediated by such cells was not shown.⁴¹ New approaches for understanding the immunobiology of GVHD are needed. Simple questions remain unanswered, such as "What are the effector and effector cells mediating GVHD in human transplant recipients?" and "What are the target cells in the various organ systems affected by GVHD?"

A promising predictive test for acute GVHD was recently developed.⁴² Donor lymphocytes were sensitized against recipient lymphocytes in vitro and cocultured with recipient skin. The coculture system showed histologic changes similar to acute GVHD and was able to predict acute GVHD. Such a test may be useful in selecting donors for transplantation and selecting the type of GVHD prophylaxis.

ISSUES RELATED TO CHRONIC GVHD IN LONG-TERM RECIPIENTS

Chronic GVHD occurs in 35% to 45% of the patients receiving HLA-identical bone marrow transplants at any time between 100 days and 15 months postgrafting.⁴³ The clinical picture of chronic GVHD resembles autoimmune diseases such as scleroderma, systemic lupus erythematosus, Sjögren's syndrome, lichen planus, and eosinophilic fasciitis. This analogy is supported by the findings of circulating autoantibodies and deposits of immunoglobulin and complement at the dermal-epidermal junction.⁴⁴⁻⁵⁰ The manifestations of chronic GVHD include skin lesions, severe buccal mucositis, keratoconjunctivitis, esophageal and vaginal strictures, large intestinal involvement, chronic liver disease, and failure to thrive.

Increasing patient age at transplant is associated with an increased incidence of chronic GVHD. The presence of nonspecific suppressor cells in the mixed lymphocyte culture assay^{51,52} and the increased suppressor T cell activity in immunoglobulin production assays may reflect similar abnormal nonspecific regulatory phenomena in recipients with chronic GVHD. HLA nonidentity between recipient and marrow donor increased the risk of varicella zoster infections after marrow grafting, and the presence of chronic GVHD predisposed the recipient to late varicella zoster infections.⁵³ The increased incidence of varicella zoster infections may be related to the immunosuppressed state of those with chronic GVHD.

The association between acute and chronic GVHD and their responses to immunosuppressive therapy suggest that chronic GVHD is mediated by lymphocytes reacting against host antigens. In vitro studies support this speculation. Donor-derived lymphocytes from long-term recipients with chronic GVHD exhibited unidirectional mixed lymphocyte culture reactivity to cryopreserved host lymphocytes and cytotoxic activity directed at host fibroblasts.^{54,55} The unidirectional mixed lymphocyte culture reactivity was present in a higher proportion of recipients with chronic GVHD than in long-term recipients without chronic GVHD.⁵⁴ These cells were not detected in healthy recipients presumably due to the presence of specific suppressor T cells that suppress the immune reaction of donor cells to trinitrophenol-modified host cells.⁵⁶ The presence of nonspecific cells to unrelated cells in mixed lymphocyte cultures and increased suppressor T cell activity after pokeweed mitogen activation in half of the recipients with chronic GVHD may be an attempt by the newly developing immune system to compensate for its overactivity directed at non-HLA antigens. Lack of appropriate thymic reeducation of donor lymphocytes by a defective, damaged, or histoincompatible thymic microenvironment may contribute to the pathogenesis of chronic GVHD.

MUCOSAL DEFENSE SYSTEM

Although difficult to quantify, chemoradiotherapy damage to the mucosa in the marrow recipient is a major insult to the host immune system. The mucosal defense systems are then further damaged by acute GVHD. Alterations in the integrity of mucosal linings and the impaired local IgA

secretion by B cells in the linings of the intestinal, respiratory, and urinary tracts may provide easy access for invading pathogens. It is clear from the types of infections that occur and the timing of such infections that mucosal immunity ("the first line of defense") is severely impaired in the first 100 days postgrafting and continues to be impaired in recipients who have chronic GVHD. Skin biopsies from long-term recipients with chronic GVHD show histologic evidence of sialadenitis, stomatitis, or both with sialodochitis.⁵⁷ Salivary gland involvement was associated with decreased or absent levels of IgA, decreased salivary flow rates, and increased concentrations of sodium, albumin, and IgG.⁵⁷ If one adds these findings to the low serum IgG and IgM levels in the first several months after grafting and serum IgA levels that remain low for more than one year postgrafting in the majority of marrow graft recipients,^{7-9,12,13} it is not surprising that fatal infections occur despite protection afforded by antibiotics, laminar air flow rooms, granulocyte transfusions, and immune globulin transfusions.

PHAGOCYTIC AND ACCESSORY CELL FUNCTIONS

Studies on neutrophils show that their numbers normalize early, but they have impaired chemotaxis up to four months postgrafting.⁵⁸⁻⁶⁰ Neutrophil iodination capacity, a measure of the ability of neutrophils to phagocytize and activate oxygen-dependent mechanisms of intracellular killing, were not different from normal controls during the early period.⁵⁸ These findings partially explain why fungal and bacterial infections are common postgrafting when neutrophils are absent and neutrophil chemotaxis is impaired.

Peripheral blood monocytes from marrow recipients can be shown to be of donor origin by cytogenetic markers as early as 41 days postgrafting.⁶¹ Tissue-fixed macrophages in the lung and liver are of donor type by day 80 postgrafting.^{62,63} Monocytes have been reported to exhibit normal chemotaxis, adherence, phagocytosis, and cytotoxicity early postgrafting.⁶⁴

Studies on the antigen-presenting accessory cell functions of peripheral blood monocytes from marrow recipients show that monocytes can successfully present killed *Escherichia coli* bacteria in proliferation assays.⁶¹ Enriched monocyte populations from the majority of short-term and long-term marrow recipients were capable of providing accessory cell function in T cell-dependent pokeweed mitogen-stimulated immunoglobulin production.⁶⁵ Suppressor activity in pokeweed mitogen-stimulated immunoglobulin production mediated by monocytes was detected in only a few marrow recipients with chronic GVHD.⁶⁵ Interleukin 1 (IL 1) production by monocytes from marrow recipients is normal by five to six weeks postgrafting.⁶⁶ By six weeks posttransplant, monocyte functions are generally intact.

CYTOTOXIC FUNCTIONS OF LYMPHOCYTES

Impaired T cell-mediated or natural killer (NK) cell-mediated cytotoxicity directed at viruses may account for nearly one half of the allogeneic recipients developing infections with the herpes group of viruses postgrafting. Cytomegalovirus (CMV) accounts for roughly 60% of the inter-

stitial pneumonias that occur during the first three months postgrafting.⁶ Attempts to prevent or treat CMV pneumonias with various agents or CMV immune globulin have met with variable success.⁶⁷⁻⁷²

The role of NK cells directed at viruses and cytotoxic T cells directed at viruses during the immediate postgrafting period remains controversial. Most studies show that NK activity against K562 or Chang targets, lectin-dependent cellular cytotoxicity, and antibody dependent cellular cytotoxicity recover rapidly to normal levels in the majority of marrow recipients by 30 to 50 days postgrafting,⁷³⁻⁷⁵ but up to 20% of the marrow recipients continue to have deficient cytotoxic functions a year or more postgrafting.⁷³ One study showed that HLA-restricted CMV-specific cytotoxic T lymphocyte responses to CMV and natural killer cell responses to CMV develop postgrafting and that low or nonexistent cytotoxic responses occur at the onset of CMV infections in recipients who develop fatal infections.⁷⁴ Another study showed that NK activity fell from normal levels when recipients developed severe viral infections, and there was a correlation between the incidence of acute GVHD and high NK activity.⁷⁵ Other studies show no significant correlations between cytotoxic activity and clinical findings such as infections, GVHD, and recurrent leukemia.⁷³

Impaired cell-mediated lympholysis (CML) occurred in cells from recipients with acute and chronic GVHD, whereas most short-term and long-term recipients without GVHD had normal CML responses.⁷⁶ Interleukin 2 (IL 2) production was reduced in short-term recipients with acute GVHD.^{76,77} The addition of IL 2 to the mixed lymphocyte cultures during the sensitization phase could restore CML reactivity in lymphocytes from recipients with acute GVHD but not in lymphocytes from recipients with chronic GVHD.⁷⁶ One simple explanation for the heterogeneous and conflicting reports on cytotoxic cell function would be the differences in the techniques used to study recipients and the differences in the study populations. A unifying and biologically relevant explanation is that the current studies may reflect a spectrum of maturational stages of cytotoxic cells.

T CELL-MEDIATED IMMUNITY EARLY POSTGRAFTING

Donor-derived T and B cells repopulate the peripheral blood in allogeneic marrow recipients within the first three months. However, repopulation of T cell subsets as defined by surface phenotypic markers using monoclonal antibodies or Fc-receptor rosetting occurs at different rates for both subsets and individual recipients. The consensus of most studies using phenotypic markers for the helper-inducer phenotype (CD4) and the suppressor/cytotoxic phenotype (CD8) postgrafting is that the absolute number of CD4 cells is lower than normal in the first three to six months postgrafting, and the absolute number of CD8 cells is higher than normal in the first six months postgrafting resulting in lower than normal helper-inducer/suppressor-cytotoxic cell ratios.⁷⁸⁻⁸⁴ Similarly, the proportions of Fc-IgG receptor-bearing T cells (T_G, suppressor phenotype) were increased, and the proportions of Fc-IgM receptor-bearing T cells (T_M, helper phenotype) were decreased early after transplant

leading to decreased T_G/T_M ratios observed in recipients up to three years posttransplant.⁸⁵ Immature T cells or thymocytes (OKT10) were found circulating in small numbers up to six to 12 months postgrafting.^{78,80,81} The expression of HLA-DR (Ia-like) antigens was increased after three months postgrafting.⁸¹ Several groups have shown associations between viral infections and decreased CD4/CD8 ratios,^{81,84} but other groups have not shown such an association.^{79,80} In autologous marrow graft recipients it has been suggested that low CD4/CD8 ratios may be predictive of CMV infections.⁸⁶ Some groups showed a correlation between low CD4/CD8 ratios and acute GVHD.^{82,83} However, other studies indicate that most short-term autologous marrow recipients have low CD4/CD8 ratios.⁸⁷ Long-term recipients with chronic GVHD persist in having low proportions of CD4 cells and high proportions of CD8 cells.^{11,78,82,88}

The expression of IL 2 receptors, identified by the MoAb anti-TAC,^{89,90} on T cells from marrow recipients less than six months postgrafting is controversial. One group did not find IL 2 receptor positive T cells,⁸¹ whereas a more recent report showed >25% of the cells in the peripheral blood of marrow recipients undergoing graft rejection or acute GVHD were IL 2 receptor positive.⁹¹ In our studies peripheral blood lymphocytes from five of 12 short-term recipients with or without GVHD between 45 and 83 days postgrafting expressed IL 2 receptors ranging from 1.0% to 12.3% (Lum, unpublished). The expression of IL 2 receptors may represent in vivo activation of T cells by any number of clinical events or treatments. Investigators have found that OKT10 and Ia were expressed on the T cells from short-term recipients.^{78,80,81,84} Inverted CD4/CD8 ratios and the expression of OKT10 and Ia antigens may simply reflect immature and/or regenerating T cell populations early after marrow grafting with CD8 cells arising first. The effects of chronic GVHD on this sequence of events are discussed later.

In vivo cellular immunity as measured by delayed-type hypersensitivity is impaired in the first 100 days postgrafting.⁹² In vitro proliferative responses after stimulation with mitogens, specific antigens, and alloantigens measured by ³H-thymidine uptake are low during the first 100 days postgrafting.^{7-10,12}

A number of investigators have used a variety of in vitro systems for testing the ability of T and B cells from short-term marrow recipients to produce immunoglobulin after nonspecific activation with agents such as pokeweed mitogen or Protein A from *Staphylococcus aureus*.⁹³⁻⁹⁸ T cells from two thirds of the recipients did not provide T cell helper activity and had increased suppressor T cell activity.⁹⁵ More recent studies designed to identify T cell subsets responsible for abnormalities in T cell function show that CD4 cells failed to help and frequently exhibited suppression, and CD8 cells did not routinely exert suppressor activity.⁹⁹ Overall, T cells failed to help their B cell counterparts during the early period postgrafting to produce immunoglobulin. Such functional data indicate that T cells are not ready to perform in a concerted fashion with B cells early after grafting. In addition, T cells responsible for suppressor activity directed at Epstein-Barr virus (EBV)-driven B cell clones may not function, thereby permitting the development of B cell

lymphomas early after transplantation in those receiving T cell-depleted bone marrow. This notion is supported by observations in our laboratory showing that EBV-driven immunoglobulin secretion by donor B cells is often not suppressed by recipient T cells, whereas normal T cells do suppress the EBV-driven immunoglobulin secretion response of B cells.¹⁰⁰

T CELL-MEDIATED IMMUNITY IN LONG-TERM RECIPIENTS

After one year postgrafting, marrow recipients without chronic GVHD normalize their CD4/CD8 ratios, but those with chronic GVHD have persistently elevated proportions of CD8 cells with decreased proportions of CD4 cells in their peripheral blood.^{11,81,88} Low numbers of circulating CD4 cells in recipients with chronic GVHD may be a result of selective in vivo sequestration and/or depletion by ongoing GVHD reactions occurring in the skin, liver, or gut. This inverted ratio is associated with a number of in vitro findings described in the following sections.

Greater than 90% of marrow recipients make at least one positive response to a battery of five recall skin test antigens by four years postgrafting. Proliferative responses to mitogens, alloantigens, and specific antigens return to normal or near normal values after six months to one year postgrafting in recipients without chronic GVHD.⁹²

Early studies performed in the pokeweed mitogen system using T cells from long-term marrow recipients with and without chronic GVHD showed that roughly one half of those with chronic GVHD had T cells that failed to provide helper activity and exhibited excessive suppressor activity.^{88,101,102} Fractionation of T cells from recipients with chronic GVHD into Fc-IgG receptor positive T cells (T_H^+) and Fc-IgG receptor negative T cells (T_G^-) showed heterogeneous helper and suppressor activity in both T cell subsets.¹⁰³ Such T cell defects were less frequent in healthy long-term survivors. One study showed increased spontaneous Ig secretion by B cells from recipients with chronic GVHD.¹⁰²

Later studies showed that excessive suppressor T cell activity, for the most part, was due to increased proportions of CD8 cells. CD4 cells from one third of the patients with chronic GVHD did not provide helper activity,^{88,104} whereas CD4 cells from healthy long-term survivors consistently provided helper activity in the pokeweed mitogen system. Studies using immunoglobulin production assays show heterogeneous functional responses in the CD4 and CD8 T cell subsets from recipients with and without chronic GVHD.

In a recent study, tetanus toxoid, herpes simplex type 1 virus, and pokeweed mitogen were used to develop functional profiles of CD4 and CD8 subsets from long-term marrow graft recipients.¹⁰⁵ The study showed that immune reconstruction occurs in a variable fashion associated with extremely heterogeneous T and B cell subset functions. Recipients with chronic GVHD had delayed reacquisition of normal function within each T cell subset.¹⁰⁵ The spectrum of functional responses found in the T cell subsets may reflect developmental stages within each phenotypic lineage postgrafting. However, these nonspecifically stimulated functional assays of immunoglobulin production did not correlate

with *in vivo* specific antibody titers to tetanus toxoid or herpes simplex virus on a per patient basis.¹⁰⁵

B CELL-MEDIATED IMMUNITY EARLY POSTGRAFTING

Levels of IgG and IgM in the serum return to normal after three to four months postgrafting, but levels of IgA may remain low for years.^{7-10,12} IgE levels have been reported by several groups to be elevated in association with acute GVHD.¹⁰⁶⁻¹⁰⁸ Levels of the total hemolytic complement, the third component of complement, and the fourth component of complement are normal in the first three months postgrafting.^{12,28} Allogeneic and syngeneic marrow recipients have severely depressed antibody responses to immunizations with the neoantigens keyhole-limpet hemocyanin, pneumococcal polysaccharide type 3 antigen, and bacteriophage OX174 in the first six months postgrafting.^{12,13,15} An early study used specific antibody titers to keyhole-limpet hemocyanin and yellow fever virus as immunologic probes in a short-term marrow recipient to prove lymphoid engraftment after transplantation from an identical twin donor who was immunized to keyhole-limpet hemocyanin and yellow fever virus pretransplant.¹⁰⁹ The recipient developed antibody titers to keyhole-limpet hemocyanin. Recent data from this and other laboratories show that IgG antibody titers to recall antigens such as tetanus toxoid, diphtheria toxoid, and measles virus can be detected within the first 100 days postgrafting with or without booster immunizations to the test antigens.¹¹⁰⁻¹¹² Two hundred and twenty-one of 235 (94%) short-term patients had titers to tetanus toxoid, 176 of 232 (76%) short-term recipients had titers to diphtheria toxoid, and seven of eight (87%) short-term recipients had titers to measles virus¹¹² (Lum, unpublished). Specific antibody titers to recall antigens in short-term marrow recipients were in the normal range without booster immunizations, whereas responses to primary and secondary immunizations with neoantigens postgrafting were severely depressed during the early period postgrafting.

The source of the specific antibodies to recall antigens during the first 100 days remains unclear. The likely source of antibody is B cells of donor origin. However, persistent host antibodies, persistent host B cells producing antibody, passively acquired antibody via blood product support, and the stimulation of already precommitted memory B cells transferred from the donor may all contribute to antibody titers to recall antigens. Antigen-specific helper activity may not be required for *in vivo* antibody synthesis by precommitted B cells. This hypothesis is supported by one report that shows that titers to tetanus toxoid and hepatitis B are detectable in short-term recipients who received T cell-depleted marrows by immunizing donors alone or both the donors and the recipients pretransplant.¹¹³

The probability of detecting host-type isohemagglutinin in ABO-incompatible marrow graft recipients is less than 0.20 by day 80 postgrafting and is zero by day 120 postgrafting.¹³ Therefore, the levels of specific antibody to recall antigens detected at 100 days postgrafting suggest a major contribution produced by transferred donor B cells. Immunoglobulin allotypes of donor origin have been detected as early as 113 days postgrafting.¹¹⁴ Clearly, the synthesis of antibodies of

donor allotype must begin before this time to be detected without interference from host-type allotypes.

B cell phenotyping data in the first two months postgrafting show that B cells from allogeneic marrow recipients have normal or near normal numbers of surface immunoglobulin positive (sIg⁺) B cells as measured by polyvalent antisera directed at human immunoglobulin.^{9,10,12} However, recent phenotyping data shows the appearance of B cells bearing the CD5 T cell antigen 30 days postgrafting.¹¹⁵ The CD5⁺ B cells were present in healthy recipients. High proportions of CD5⁺ B cells are found in fetal spleen (30% to 50%).⁹¹ These B cells may represent an early stage of differentiation of normal B cells or a separate lineage.¹¹⁶ Data from this laboratory show that populations of sIgG, sIgM, sIgA, or sIgD⁺ B cells in peripheral blood lymphocytes may be absent in certain recipients (Lum, unpublished). The most likely explanation for these findings is that B cells lacking a specific surface marker may be associated with specific maturational defects. This notion is supported by a study that showed B cells from marrow recipients had higher numbers of primitive μ -determinants per B cell than normal B cells¹¹⁷; these findings are similar to those found in murine splenic B_H cells that display increased μ -determinants early in ontogeny.

B cell-enriched populations from marrow recipients in the first three months postgrafting fail to produce *in vitro* antibody after stimulation with specific or nonspecific activators in the presence of normal T cells.^{93-95,97,118} B cells from a few marrow recipients in the early period produced nonspecific immunoglobulin after EBV (T-independent) stimulation.⁹⁷ Stimulation with EBV to polyclonally activate production of IgG antitetanus toxoid antibodies (anti-TT) was not successful during the early period.¹¹⁹ Furthermore, B cells from short-term recipients failed to produce anti-TT after stimulation with tetanus toxoid in the presence of donor helper T cells.¹¹⁸

In assays for B cell activation, proliferation, and differentiation, B cells from short-term marrow recipients cannot be activated by staphylococcal aureus Cowan I bacteria (SAC) to subsequently proliferate or differentiate in the presence of normal T cell factors containing B cell growth factor (BCGF), B cell differentiation factor (BCDF), and IL 2.¹²⁰ With the exception of preprogrammed spontaneous antibody secretion, the B cells from marrow recipients seem incapable of responding to exogenous signals.

B CELL-MEDIATED IMMUNITY IN LONG-TERM RECIPIENTS

Primary and secondary responses to neoantigens (keyhole-limpet hemocyanin and bacteriophage OX174) recover to normal levels by one year in healthy recipients but remain impaired in those with chronic GVHD. Those with chronic GVHD not only have defective primary responses to bacteriophage OX174, but they fail to switch from IgM production to IgG production in secondary responses.¹³

Recent studies using recall antigens have been informative. In healthy long-term recipients, 85 of 125 (68%) studied had IgG titers to tetanus toxoid; 62 of 104 (60%) had IgG titers to diphtheria toxoid, and 12 of 18 (66%) had IgG titers to measles virus. In recipients with chronic GVHD, 79 of 166

(48%) studied had IgG antibody titers to tetanus toxoid; 40 of 136 (29%) had IgG titers to diphtheria toxoid, and 6 of 15 (40%) had IgG titers to measles virus¹¹² (Lum, unpublished). None of the recipients (ranging from one year to nine years postgrafting) were boosted to the test antigens postgrafting. Furthermore, a number of long-term recipients who received T cell-depleted marrow grafts also had detectable antibody titers to tetanus toxoid and diphtheria toxoid.¹²¹ Such data show that there was transfer of antigen-specific B cell memory from the marrow donors to the marrow recipients, and the transferred immunity persisted for years posttransplant. One report showed transfer of anti-acetylcholin-receptor immunity from a marrow donor with myasthenia gravis to the marrow recipient who developed myasthenia gravis postgrafting.¹²² Recent studies show that bone marrow mononuclear cells could produce specific antitetanus toxoid antibody after in vitro stimulation with pokeweed mitogen or tetanus toxoid with or without tetanus toxoid booster immunizations.^{123,124}

B cells from three fourths of the recipients with chronic GVHD have impaired B cell function, whereas only one third of the healthy recipients have B cell defects in in vitro immunoglobulin production systems stimulated with pokeweed mitogen.^{81,82,85,94,97,101} Furthermore, B cells from the same marrow recipient have different responses to different activators of immunoglobulin production when studied at the same time in systems activated by pokeweed mitogen, EBV, tetanus toxoid, and herpes simplex type 1 virus.¹⁰⁵ These suggest that there are functionally distinct groups for each activator of polyclonal immunoglobulin production that mature at different times postgrafting. Although the above studies document B cell failure, none specify the types of defects responsible for the lack of immunoglobulin secretion. These results provided the rationale in our laboratory for developing assays for assessing antigen-specific immunity and identifying the types of B cell defects that occur in marrow recipients.

Our latest studies focused on antigen-stimulated specific antibody synthesis in lymphocytes obtained from long-term recipients. Anti-TT synthesis was induced using a tetanus toxoid-specific system.¹²⁵ An early study showed that tetanus toxoid-specific T cell helper activity can be detected in cocultures of recipient T cells and donor B cells.¹¹⁸ However, recipient B cells cocultured with donor T cells failed to produce anti-TT. The results of this study suggest that antigen-specific T cells can be transferred in marrow transplantation. In another study designed to rule out the possibility of low antigen-specific B cell precursor frequency, we used high numbers of T and B lymphocytes per culture and found that only a minority of marrow recipients had B cells capable of producing in vitro anti-TT when increased numbers of lymphocytes were placed in culture.¹²⁶ These studies demonstrated that antigen-specific precursor frequency is low in long-term marrow recipients. Roughly one third of long-term marrow recipients had B cells capable of producing anti-TT after EBV stimulation.¹¹⁹ These data suggested that the majority of B cell defects were primarily due to deficient function rather than a low antigen-specific B cell precursor frequency.

In assays that assess nonspecific B cell activation, proliferation, and differentiation, B cells from long-term marrow recipients exhibited two patterns in their B cell functions.¹²⁷⁻¹²⁹ B cells from some recipients could be activated with SAC but had decreased proliferative and differentiative responses to T cell supernatants containing B cell growth and differentiation factors. B cells from other recipients could proliferate but could not synthesize immunoglobulin after SAC activation and stimulation with T cell supernatants. Healthy long-term recipients had fewer, less severe B cell defects in these B cell function assays. Such B cell defects were not observed in the normal control subjects. There was a high degree of correlation ($P = 0.0075$) between low IgG levels in marrow recipients and the failure of B cells from marrow recipients to synthesize IgG after costimulation with SAC and T cell supernatants.¹²⁰ These studies suggest that the normal maturation of B cells is interrupted by specific blockades at one or more stages after marrow grafting.

ATTEMPTS TO ACCELERATE RECONSTITUTION

Attempts to accelerate the immune reconstitution with the use of thymic tissue transplantation¹³⁰ or thymosin fraction V¹³¹ have not been successful nor have they influenced the development of chronic GVHD thought to be due to low or absent thymic tissue function in older (>30 years) marrow graft recipients. However, the results of such studies indicate that future administration of thymic hormones or related molecules may be done safely. Other hormones that might be considered for use in immune reconstitution are thymosin alpha-1,¹³² the pentapeptide thymopoietin,¹³³ and serum thymic factor.¹³⁴ Varicella zoster-specific transfer factor did not reconstitute varicella zoster-specific immunity or prevent recurrent varicella zoster infections when given between day 50 and day 64 postgrafting.¹³⁵

The development and availability of recombinant T and B cell growth factors will permit clinicians to administer specific molecules to determine if certain T and B cell immune defects could be constituted in marrow recipients and other patients with immune deficiency disorders.

REIMMUNIZATIONS FOR MARROW RECIPIENTS?

Most transplant centers have not reimmunized patients postgrafting. However, questions that are frequently asked include: (1) Do transplant recipients need to be routinely reimmunized to the childhood series of immunizations? (2) Should they be immunized to specific pathogens such as *Streptococcus pneumoniae* or *Hemophilus influenzae*? (3) Should live viral vaccines be used in the reimmunization of marrow recipients?

Recent studies that show transfer of antigen-specific immunity from the marrow donors to marrow recipients suggest that a significant number of marrow recipients will develop specific antibody titers to recall antigens without reimmunization to the specific antigens. Obviously, those who develop antibody titers need not be reimmunized to the specific antigens. However, those who do not develop antibody titers need to be considered for reimmunizations with diphtheria toxoid, tetanus toxoid, and inactivated polio vac-

cines and followed for the development of specific antibody titers. Herd immunity and transferred specific immunity may help explain why more marrow recipients do not succumb to measles, polio, tetanus, diphtheria, and pertussis infections. Vaccinations with live viral vaccines are not recommended. The inactivated Salk polio vaccine would be useful for those at risk during outbreaks of polio. The value of specific viral or bacterial vaccines (herpes vaccine, Pneumovax) in marrow recipients remains debatable. In some immunodeficiency states the efficacy of such immunizations is poor.

Furthermore, it is unclear how many immunizations with a specific vaccine would be necessary to obtain specific immune responses in the transplant population. Those undergoing reimmunization schedules would likely require two or three immunizations before they would develop circulating antibody titers. Recipients being treated for active chronic GVHD should have their immunizations deferred until their disease is resolved, since it is likely that they would not respond to immunizations. Titers to the specific antigen should be followed to determine if an immune response was obtained.

RECAPITULATION OF ONTOGENY

Immune reconstitution after human marrow grafting has offered a unique model for studying stages of normal immune ontogeny, transfer of immunity, and immune defects that may parallel those seen in immunodeficiency disorders. The kinetics of immune reconstitution follow a general pattern. First to appear are cytotoxic and phagocytic cells. More mature systems characterized by highly specialized cellular functions such as proliferation, helper activity, differentiation, lymphokine production, and antibody biosynthesis appear later. The latter functions require complex and finely tuned cell-cell interactions mediated by cell contact and soluble factors. As the elements of the immune system regain their roles, healthy long-term recipients develop immunocompetence sooner than those with chronic GVHD. During the recapitulation of ontogeny over a time period ranging up to four years postgrafting, a spectrum of functional and nonfunctional stages within various T and B cell phenotypes are expressed. The development of immunocompetence includes antigen-specific immunity transferred from the marrow donor to the marrow recipient as shown by (1) the detection of specific antibody titers to recall antigens and (2) the ability of T and B cells from long-term recipients

to produce specific recall antibodies *in vitro*. The overall pattern of immune reconstitution is delayed in recipients with chronic GVHD. The delay may be due to failure of lymphocyte subsets to progress through certain developmental stages. On the other hand, the syndrome of chronic GVHD with autoantibody formation and other autoimmune phenomena may be a result of immune dysregulation due to unregulated overactivity of certain lymphocyte subsets. (Perhaps with appropriate thymic education this would not occur.)

For the sake of discussion, the immune reconstruction process was artificially divided into early and late phases and into the various cell types. However, one must emphasize that synchronization of various components of the lymphoid system is essential for complete reconstitution. Without appropriate synchronization of the various elements of the immune system the result would be immune dysfunction. Of the multiple factors studied for their effects on immune reconstitution, time continues to be a key factor affecting the reestablishment of immunocompetence. It remains unclear whether certain immune deficits lead to the development of GVHD or immune deficits are a result of GVHD or its treatment. Furthermore, the effects of T cell depletion of bone marrow or HLA-mismatched transplantation on immune reconstitution are unknown and remain areas of active investigation.

FUTURE DIRECTIONS

The questions that emerge from this review suggest future laboratory and clinical investigations revolving around the following issues: (1) augmenting specific immunity to pathogens before and/or after transplant by administering vaccines or vaccine substitutes, (2) the clinical use of growth factors to restore specific T and B cell functions, (3) the use of adoptively transferred donor-derived cytotoxic T cell lines directed at specific viral or bacterial pathogens to treat recipients with specific infections, and (4) the insertion of specific genes into the bone marrow inoculum using retroviral vectors to reconstitute specific immune defects. These maneuvers are approaches that may accelerate immune reconstitution and shorten the immunodeficiency experienced by marrow recipients.

ACKNOWLEDGMENT

I would like to express my appreciation to Jan Noges for her dedication and care in the preparation of this manuscript.

Plasminogen Activator Inhibitors

By E.D. Sprengers and C. Kluft

PROTEOLYTIC DEGRADATION of fibrin clots (fibrinolysis) is mediated by the enzyme plasmin. Plasmin is formed in the circulation from the inactive precursor plasminogen through the proteolytic action of plasminogen activators (PA).^{*} For both plasmin and plasminogen activators specific inhibitors are present: α_2 -antiplasmin and plasminogen activator inhibitors (PA-inhibitors), respectively (Fig 1).

Proteinase inhibitors represent nearly 10% of the total protein in blood plasma.¹ They control a variety of critical events associated with connective tissue turnover, coagulation, fibrinolysis, complement activation, and inflammatory reactions. As a general rule, proteinase inhibitors can react with several proteinases. The attribution of a specific function to a certain proteinase inhibitor depends on its concentration and its second-order rate constant with a certain proteinase; these two parameters determine the half-life of a proteinase due to inactivation by the inhibitor. As early as 1963 Brakman and Astrup claimed the existence of PA-inhibitors by demonstrating a fibrinolytic inhibitor that did not inhibit plasmin in the blood of pregnant women.² Several reports about the presence of a specific inhibitor of PA in human plasma have appeared before 1982; however, due to the lack of appropriate kinetic data, a specific inhibitor of PA in blood plasma has never been convincingly demonstrated.^{3,4} The question has been raised whether there is a logical function for specific PA-inhibitors at all, since the activity of PA is regulated by several mechanisms such as release from the vessel wall and rapid hepatic clearance, specific interaction with fibrin (at least for tissue-type PA [t-PA]) and proteolytic activation of single-chain PA (at least for pro-urokinase). Moreover, the activity of the fibrinolytic system is strongly regulated by the abundant plasmin inhibitor α_2 -antiplasmin (0.06 mg/mL plasma). Nevertheless, the existence of specific PA-inhibitors is now no longer a matter of dispute. PA-inhibitors can already be classified in at least three immunologically different groups⁵: the endothelial cell type PA-inhibitor (PAI-1), the placental type PA-inhibitor (PAI-2), and protease nexin-I.^{*} Their function in the regulation of the activity of the fibrinolytic system is still only partly understood. This review is not meant as a historical or chronological review, but briefly summarizes what is presently known about PA-inhibitors.

TYPE 1 PA-INHIBITOR

Endothelial cell-type PA-inhibitor (PAI-1) is synthesized by endothelial cells⁶⁻¹³ and human hepatocytes in culture,¹⁴ by several hepatoma cell lines,¹⁴⁻¹⁶ granulosa cells,¹⁷ SV-40 virus-transformed human lung fibroblasts (the cell line WI-38 VA 132 RA),¹⁸ the MJZJ melanoma cell line,¹⁹ and probably by vascular smooth muscle cells²⁰; it is also found in the α -granules of blood platelets^{18,21-23} and plasma.²⁴⁻⁴⁰ This inhibitor reacts with both urinary-type plasminogen activator (u-PA) and t-PA, with a second-order rate constant of above 10^6 to 10^7 mol/L⁻¹ s⁻¹.^{24,25,27,28,30,40} The reaction of the inhibitor with these PA eventually results in the formation of sodium dodecyl sulphate (SDS)-stable complexes with a molecular mass that is 40 to 50 kilodaltons (kd) higher than the molecular mass of the free PA.^{10-14,20,22,24,27,28,31-34,36,38,40}

The PA/PA-inhibitor complex has no PA activity as such, but after SDS/Triton X-100 treatment a PA activity can be generated that is much smaller than the activity of an equivalent quantity of free PA.^{10-12,24,26-28,32-34,40,41} Whether this is due to dissociation of a small part of the PA/PA-inhibitor complex molecules induced by the SDS/Triton X-100 treatment or due to an intrinsic activity of the complex after SDS/Triton X-100 treatment is not yet clear.

Endothelial cell-conditioned medium and blood platelets contain both active and inactive (latent) forms of PAI-1.^{12,23,38,42,43} The PA-inhibitor is probably synthesized by cultured endothelial cells in an active form. Inactivation (apart from complex formation with PA) can occur in at least two different ways: by a rapid inactivation of newly synthesized PA-inhibitor upon leaving the cell, with a calculated half-life of 0.29 hour; and by a much slower inactivation in (cell-free) conditioned medium with a half-life of two to four hours at 37 °C.⁴⁴ Whether the rapid and slow inactivation processes also take place in vivo is not yet clear. The accumulation of the inactive (latent) form in 24-hour endothelial cell-conditioned medium, reaching up to a hundredfold excess of inactive over active PA-inhibitor,⁴⁵ is probably due to inactivation of actively synthesized PA-inhibitor.⁴⁴ The inactive (latent) form does not inhibit t-PA or u-PA, nor does it form complexes with these PA. This inactive form can, however, be "activated" in vitro by the action of protein denaturants such as SDS, urea, and guanidine HCl, followed by renaturation through removal of the

^{*}At their meeting of June 2, 1986, in Jerusalem, Israel, the Subcommittee on Fibrinolysis of the ICTH proposed the designation of PA-inhibitors by sequence numbers. Endothelial cell-type PA-inhibitor (nomenclature of 1985⁵) was proposed to be designated as plasminogen activator inhibitor 1 (PAI-1), and placental-type PA-inhibitor (nomenclature of 1985⁵) was proposed to be designated as plasminogen activator inhibitor 2 (PAI-2). Protease nexin I maintains its name. In this review we use the newly proposed nomenclature.

PROTEASE NEXIN

Protease nexin I has been purified to homogeneity from human foreskin fibroblast-conditioned medium.⁶⁰⁻⁶² It has a molecular mass of about 43 kd and contains approximately 6% carbohydrate. It is a broad specificity inhibitor of trypsin-like serine proteinases. It reacts rapidly with trypsin ($k_{on} = 4.2 \times 10^6 \text{ mol/L}^{-1}\text{s}^{-1}$), thrombin ($k_{on} = 6.0 \times 10^5 \text{ mol/L}^{-1}\text{s}^{-1}$), u-PA ($k_{on} = 1.5 \times 10^5 \text{ mol/L}^{-1}\text{s}^{-1}$), single-chain t-PA ($k_{on} = 1.5 \times 10^3 \text{ mol/L}^{-1}\text{s}^{-1}$), two-chain t-PA ($k_{on} = 3.0 \times 10^4 \text{ mol/L}^{-1}\text{s}^{-1}$), and plasmin ($k_{on} = 1.3 \times 10^5 \text{ mol/L}^{-1}\text{s}^{-1}$), forming 1:1 complexes with these proteinases.⁶¹ It contains a high-affinity heparin binding site; in the presence of heparin the rate of the reaction of protease nexin I with thrombin is nearly diffusion-controlled.⁶¹

Protease nexin I is synthesized by a number of anchorage-dependent cells including fibroblasts, heart muscle cells, and kidney epithelial cells.⁶³ In serum-free cultures of human fibroblasts, secreted protease nexin I suppresses the cellular sensitivity to the mitogenic action of added thrombin,^{64,65} limits activation of secreted single-chain u-PA by exogenous proteinases^{66,67} and inhibits two-chain u-PA.^{60,66}

Fibroblasts bear surface receptors that mediate the endocytosis and lysosomal degradation of proteinase/protease nexin I complexes.⁶⁷ Protease nexin I is not detectable in blood plasma. Since the second-order rate constants of protease nexin I with thrombin and trypsin are much higher than with either t-PA or urokinase, protease nexin I cannot be considered a true PA-inhibitor. Also, because data on protease nexin I concentrations are lacking, a calculation of a half-life of plasminogen activators due to inactivation by protease nexin I cannot be made.

PHYSIOLOGY OF PA-INHIBITORS

PA play a central role in a number of physiologic processes. Of these, the fibrinolytic system has received the most attention. For this reason, most literature on PA-inhibitors deals with the role of these inhibitors in the homeostasis of the circulation. Very little is known about the function of PA-inhibitors in the many other physiologic processes in which PA are involved (tissue repair, nidation, fertilization, cell proliferation, etc).

In most studies, only PA-inhibitory activity has been measured in assays based on titration of PA-inhibitors with PA. The reader should be cautioned that the interpretation of these assays is not always easy, since increased PA-inhibitory activity can be caused by either increased PA-inhibitor or decreased PA. Also in most studies immunologic data on the type of PA-inhibitor are lacking. For this reason we use in this review the vague term "PA-inhibitory activity" when more precise data are lacking. Otherwise the term will be more specified.

In pooled normal human blood plasma PAI-2 and protease nexin I are not found. About 60% of the PA-inhibitory activity is PAI-1. The remaining 40% is attributed to a so far limitedly characterized factor, designated as PA-binding protein.^{39,68}

The PA-inhibitory activity in blood plasma of healthy individuals is subject to a diurnal fluctuation; lowest values

are found at 3:00 PM.⁶⁹ Moreover, there is a large interindividual variation of plasma PA-inhibitory activity levels (at 9:00 AM) ranging from 0.0 to 1.3 nmol/L.^{18,25,27-30,39} On the other hand, the 9:00 AM value of plasma PA-inhibitory activity of a certain individual is constant for at least several weeks (Sprengers et al, unpublished results, January 1986). As mentioned before, the cellular origin(s) of the plasma PA-inhibitor has not yet been established.

In vitro, PAI-1 is not stable at 37°C. Incubation of endothelial cell-conditioned medium, partly purified inhibitor, or plasma at this temperature leads to a first-order decrease of PA-inhibitory activity with a half-life of two to four hours.^{23,68,70} Activated protein C and thrombin inactivate the PA-inhibitory activity in endothelial cell-conditioned medium, an effect that is at least partly due to a direct effect of activated protein C (and thrombin) on the inhibitor.⁷⁰⁻⁷³ Activated protein C can form 1:1 complexes with PA-inhibitor.⁷² This process may contribute to another linkage of the coagulation and the fibrinolytic system. The antithrombotic effect of activated protein C mediated by inhibiting the coagulation pathway may thus be enforced by its profibrinolytic potential.

PA-inhibitory activity is very rapidly cleared from the circulation; half-lives of seven minutes in the rabbit⁷⁴ and 3.5 minutes in the rat have been reported.⁷⁵ The inhibitory activity is cleared at a much slower rate during liver ligation, suggesting that clearance takes place primarily in the liver, as is true also for PA.⁷⁵ It is interesting to note that though the steady state level of PA-inhibitor is several orders of magnitude lower than that of the major plasma proteinase inhibitors, this short half-life suggests that the rate of synthesis of PA-inhibitor is approximately of the same order of magnitude as of the major plasma proteinase inhibitors.

PAI-1 in blood plasma behaves as an acute-phase reactant protein.^{76,77} PA-inhibitory activity rapidly increases after major surgery, myocardial infarction, and severe trauma. We observed that PA-inhibitory activity was only increased on the first postoperative day, thus being the most rapidly reverting acute-phase reactant protein described so far.⁷⁷ Other authors observed a much more slowly reverting pattern, however.⁷⁶ According to the latter authors, the acute-phase response parallels the response of cortisol after extensive surgery.⁷⁸ The administration of adrenocorticotropin (ACTH), however, induces cortisol to the same extent while leaving PA-inhibitory activity unaffected. This excludes a simple cause-effect relationship between increased cortisol and PA-inhibitory activity levels.⁷⁸

PA-inhibitory activity in plasma is also induced by infusion of a single dose of bacterial wall lipopolysaccharide (endotoxin) or interleukin-1.^{74,79} The increase is optimal in about four hours and is reverted within 24 hours. Lipopolysaccharide and interleukin-1 added to endothelial cell culture yield a tremendous increase in PA-inhibitory activity in the conditioned medium of the endothelial cells.^{74,79,80} It is significant that interleukin-1 does not increase PA-inhibitory activity in the conditioned medium of hepatocytes and the human hepatoma cell line Hep G2, suggesting endothelial cells rather than liver as the source of increase in PA-

inhibitory activity in plasma by the acute-phase reaction mediator interleukin-1.⁷⁹ Thrombin added to confluent monolayers of human endothelial cells resulted in a sixfold increase in PA-inhibitory activity in 24-hour-conditioned medium, an effect that was dependent on RNA and protein synthesis.⁸¹ Although PA-inhibitor antigen was not assessed in this study, the authors suggest that because t-PA antigen was also increased, the increase in PA-inhibitory activity was due to an increased amount of PA-inhibitor antigen. Since thrombin inactivates PA-inhibitory activity in endothelial cell-conditioned medium⁷⁰ this observation can only be explained by assuming that the increased rate of synthesis of PA-inhibitor is higher than the increased rate of inactivation. Indeed, we recently demonstrated that low concentrations of thrombin added to endothelial cell cultures increase both PAI-1 antigen and activity in the conditioned medium, whereas high concentrations of thrombin increase PAI-1 antigen but decrease its activity in the conditioned medium due to proteolytic degradation of the inhibitor (Van Hinsberg et al, unpublished data, September 1986).

Long-term oral administration of the synthetic anabolic steroid stanozolol to human volunteers decreases the PA-inhibitory activity in blood plasma.⁸² At least 3 weeks are required for maximal suppression of PA-inhibitory activity using a dosage of 10 mg/day.⁸² Treatment with stanozolol, 10 mg orally per day for 2 weeks preoperative, significantly enhanced the fibrinolytic activity before surgery but did not prevent the decline in fibrinolytic activity which occurs after surgery.⁸³ In cell culture the synthetic corticosteroid dexamethasone induces PA-inhibitor in HTC rat hepatoma cells.^{15,16} However, in the human hepatoma cell line Hep G2 dexamethasone does not influence the secretion of PAI-1.¹⁴

During pregnancy, PA-inhibitory activity gradually increases up to tenfold at the end of the third trimester.⁸⁴⁻⁸⁶ Postpartum it rapidly returns to prepregnant values. In "at risk" pregnancies (preeclampsia, suspected fetal growth retardation, diabetes mellitus, thrombosis and/or a previous history of thrombosis) a considerably wider range of PA-inhibitory activities, including much higher values, is observed.⁸⁴ Using an immunologic assay, a gradual increase in PAI-2 has been reported during pregnancy, yielding values up to 100 $\mu\text{g}/\text{mL}$ in the third trimester and rapidly returning to nonpregnant values after delivery.⁵⁹ Moreover, by immunoadsorption using a monoclonal anti-PAI-2 antibody, PA-inhibitory activity can be isolated from pregnancy plasmas, suggesting that PAI-2 in pregnancy plasmas is at least partly active.⁵⁹ Unfortunately, in this study no data on the molecular forms or specific activity (units/mg antigen) of the PA-inhibitor are given; so a precise interpretation of the data, ie, whether all the antigen represents active PA-inhibitor, is not possible. Our results indicate that the increase in PA-inhibitory activity during pregnancy as assessed by a titration assay can be almost fully quenched by a specific anti-PAI-1 antibody (Sprengers et al, unpublished data, April 1985).

Several authors studied associations of PA-inhibitory activity levels with certain states of disease. The most intensively studied pathologic state so far is deep venous thrombosis. Three groups independently established that

deep venous thrombosis is frequently (but not necessarily) associated with high PA-inhibitor levels.⁸⁷⁻⁹⁰ Paramo et al recently found that preoperative levels of PA-inhibitory activity were significantly higher in patients that developed postoperative deep venous thrombosis.⁸⁹ On the other hand, deep venous thrombosis is also frequently associated with an impaired release of t-PA from the vessel wall.^{87,88} These data indicate that impaired fibrinolysis can play a role in the pathogenesis of deep venous thrombosis. In patients with myocardial infarction several investigators have found an increased PA-inhibitory activity together with a decreased level of t-PA activity or antigen.^{29,91-94} In patients with coronary artery disease, the increase in the level of the PA-inhibitory activity did not correlate with the severity of the disease, however.⁹⁵ High PA-inhibitory activity levels are positively correlated with hyperlipoproteinemia.⁹⁶ Other authors found a correlation between high PA-inhibitory activity and levels of serum triglycerides.⁹³ Juhan-Vague et al found increased PA-inhibitory activity levels in the plasma of critically ill patients with a variety of diseases: pancreatitis (four of eight), liver disease (three of eight), malignancy (five of 26), myocardial infarction (five of 28), and deep venous thrombosis (two of nine).²⁹ Kruithof et al also reported an increased PA-inhibitory activity in an even wider variety of hospitalized subjects.⁹² To the contrary, in terminal renal insufficiency, either in patients with nonfunctioning kidneys *in situ* or without kidneys, PA-inhibitory activity was not significantly different from normal values.⁹⁷

The general picture emerging is that increased PA-inhibitor levels in blood plasma is indicative of acute illness as such, and that it is not associated with a special type of disease. In no case has a cause-effect relationship between increased PA-inhibitor levels and a certain disease been convincingly demonstrated, although at least in the case of deep venous thrombosis PA-inhibitory activity might have some prognostic value.⁸⁹

In normal human blood at least two pools of PA-inhibitory activity are present.²³ One pool is the (platelet-poor) plasma pool that shows a very rapid turnover and for which the normal values show a very large interindividual variation ranging from 0.0 to 1.3 nmol/L. The other pool is the platelet PA-inhibitor pool that probably shows a turnover of the order of magnitude of the turnover of platelets themselves (half-life three to four days) and for which the normal values show a much smaller range (mean: 6.7×10^{-14} mole/platelet; SD = 3.0×10^{-14}).²³ It can be calculated that in a given volume of blood the PA-inhibitory activity in the platelets is about four times higher than in the plasma.²³ The platelet PA-inhibitory activity is probably present in the α -granules^{21,22} and is indistinguishable from PAI-1 in endothelial cells.²³

During coagulation, the PA-inhibitor derived from platelets may play a very important role in protecting the blood clot against premature lysis. The high concentration of activated platelets in a blood clot may yield a local PA-inhibitor concentration that is several orders of magnitude higher than the value in plasma and would prevent too-sudden lysis. Instability of the PA-inhibitor at 37 °C (*in vitro* half-life about two hours) and inactivation by activated

protein C and thrombin may result in a gradual disappearance of the inhibitor from the clot. Subsequent diffusion of PA into the clot may result in clot lysis. Plasma PA-inhibitory activity might serve in systemic PA-activity control, preventing the unwanted action of PA under resting conditions.

The role PA-inhibitors play in thrombolytic therapy with PA remains to be established. A simple calculation shows that in order to maintain a steady-state concentration of PA-inhibitor of 1.0 nmol/L with a hypothetical half-life of ten minutes in man, a rate of synthesis of 0.45 mg/hr is required. This is far less than the amount of t-PA (up to 60

mg/hr) that is administered by intravenous injection as thrombolytic therapy to patients with myocardial infarction.^{98,99} This amount of PA-inhibitor as such is probably not a major factor in the success of thrombolytic therapy. On the other hand, since data on PA-inhibitors during thrombolytic therapy are presently lacking, conclusions cannot be drawn.

ACKNOWLEDGMENT

Drs E.J.P. Brommer, J.J. Emeis, V.W.M. van Hinsbergh, T. Kooistra and J.H. Verheijen from our institute, who are all involved in studies on PA-inhibitors, are acknowledged for support in writing this manuscript.

Successful Graft-Versus-Host Disease Prevention Without Graft Failure in 32 HLA-Identical Allogeneic Bone Marrow Transplantations With Marrow Depleted of T Cells by Monoclonal Antibodies and Complement

By P. Hervé, J.Y. Cahn, M. Flesch, E. Plouvier, E. Racadot, A. Noir, Y. Couteret, G. Goldstein, A. Bernard, R. Lenys, J.L. Bresson, R. Leconte des Floris, and A. Peters

Thirty-two patients with acute leukemia, chronic granulocytic leukemia, or multiple myeloma received a T lymphocyte-depleted HLA-identical marrow. After being treated with pan-T monoclonal antibodies (MoAbs) and one round of baby rabbit complement, the mean percentage of T cell depletion was $94\% \pm 4\%$. The number of residual viable T cell infused to the patient was $0.99 \pm 0.65 \times 10^6$ per kg body weight. The patients were conditioned with fractionated total body irradiation (TBI) (12 Gy) preceding high doses of cyclophosphamide (120 mg/kg). Methotrexate was used as an additional immunosuppressant in the first ten patients. For the following 22 patients no posttransplant immunoprophylaxis was administered. Eight patients died within three months due to complications related to

transplantation. Engraftment was achieved in all evaluable patients, and no patient has a late graft failure. The proof of total chimerism was established in 24 patients. Twenty-four of 27 evaluable patients (88%) did not have an acute graft-versus-host disease (GVHD) greater than grade 0 to 1. Two patients had a grade 2 (skin only), and one patient had a grade 4 acute GVHD (the latter had only 80% of T cell depletion). A medullary relapse occurred in 11 patients (nine of them had previously been defined as "high risk leukemia"). Our data suggest that it may not be necessary to deplete nearly all T cells to prevent acute GVHD in recipients of HLA-identical marrow.

© 1987 by Grune & Stratton, Inc.

ACUTE GRAFT-V-HOST DISEASE (GVHD) remains a major cause of morbidity and mortality in allogeneic bone marrow transplantation (BMT). Complex relationships that are not always well understood exist between GVHD and infectious complications posttransplant. Despite posttransplant immunosuppression, approximately 40% to 60% of patients who receive HLA-matched allogeneic marrow grafts develop acute GVHD. Among 1,106 patients analysed as part of the European Bone Marrow Transplant Group (EBMT), the acute GVHD grading distribution was as follows: mild in 23%, moderate in 20%, severe in 21%, and no GVHD in 36%. Chronic GVHD was observed in 24% of the patients (it was extensive in one third of these cases).¹

Murine studies have demonstrated that the removal of T cells from donor marrow can effectively prevent acute GVHD.² In man, OKT3 has not significantly reduced the incidence of acute GVHD in the first attempt to use opsonization of the T lymphocytes from the graft with monoclonal antibodies (MoAbs).^{3,4}

It has been generally considered that a near complete depletion of T cells from the marrow graft was necessary to decrease effectively the incidence of acute GVHD. Thus a large number of different methods have been reported with the aim of removing 99% of T cells from the marrow.⁵⁻⁹ Among these methods, the use of murine MoAbs specific for T lymphocyte antigens followed by complement-mediated

cytolysis is well adapted to clinical use. As a general rule, transplants following cyclophosphamide and total body irradiation (TBI) are not rejected from HLA-matched siblings, whereas the same is not true after an in vitro depletion of T cells prior to a bone marrow transplantation. According to several papers that have been published recently,^{7,10} an unusual percentage of graft failures occurs in recipients of a T cell-depleted marrow graft.

The results of an open pilot study on 32 patients transplanted with a HLA-identical bone marrow in vitro treated with pan-T MoAbs and one round of baby rabbit complement are reported here. Ten patients, included in a previously reported pilot study,¹¹ were treated with methotrexate plus T cell depletion. Acute GVHD was prevented by T cell depletion alone in 22 patients. Our aims were to evaluate the efficacy of incomplete T cell depletion as a method of preventing acute and chronic GVHD and evaluating the reconstituting ability of the T cell-depleted marrow. Our T cell depletion protocol was sufficient in preventing GVHD in most cases, and an engraftment occurred in all the study patients.

MATERIALS AND METHODS

Monoclonal antibodies and complement. According to their availability, we used different pan-T MoAbs with the intention of evaluating, in a nonrandomized study, two pan-T antibody combinations of different origins (both include a CD2 antibody). The first cocktail (OKT-pool) consisted of two murine pan-T antibodies OKT11 (CD2) and OKT3 (CD3) from Ortho (Raritan, NJ). Both MoAbs used were of IgG2 class and they were reactive with almost all mature T lymphocytes.¹² The second cocktail (CD-pool) was composed of two IgG2 class (CD5/A50 and CD7/121) and one IgM class (CD2/D66) MoAbs (A. Bernard, Institut Gustave Roussy, Villejuif, France).¹³ Neonatal rabbit complement (23 to 28 days) was prepared in our Institution (Immunological Department, Blood Transfusion Center, Besançon, France). The characteristics of the rabbit complement are detailed in Table 1.

Detection of residual T cells. Identification of the T cells coated by pan-T MoAbs was performed with indirect immunofluorescence; cells were counted either by microscope or flow cytometry. Cell viability was evaluated with trypan blue or ethidium bromide.^{14,15}

Table 1. Sources and Characteristics of Pan-T MoAbs and Complement Used in This Study

MoAbs

First combination (Ortho)

CD3/OKT3 (IgG2a) = 0.2 μg to 1 $\mu\text{g}/1 \times 10^7$ NC

CD2/OKT11 (IgG2) = 0.7 μg to 1 $\mu\text{g}/1 \times 10^7$ NC

Second combination (A. Bernard¹³)

CD2/D66 (IgGM) }
CD5/A50 (IgG2a) } 10 $\mu\text{g}/\text{L}/10^7$ NC
CD7/I21 (IgG2b) }

Rabbit Complement

White baby rabbits (23 to 28 days)

Anti-A anti-B heterohemagglutinins negative

Hematopoietic stem cell recovery ($\geq 70\%$)

Hemolytic activity (CH50 = 29.6 units $\pm$ 6.9)

Calcium level = 3.06 $\pm$ 0.156 mmol/L

T cell lysis (standardized conditions with pan-T MoAbs)

Limulus test negative

Bacteriologic and virologic controls negative

Measurements indicate mean ± 1 SD.

Approximately 200 to 500 cells were examined and counted under a Leitz fluorescent microscope.

Bone marrow processing and ex vivo treatment. Bone marrow was aspirated from the iliac crests and from the sternum (2 mL per aspirate to avoid peripheral blood contamination). Our protocol has been previously reported^{11,16} and is summarized in Fig 1. This procedure takes approximately six hours and 30 minutes to complete.

Patients' characteristics. A total of 32 patients (18 males, 14 females; 19 adults, 13 children) were included in our open pilot study. The median age was 20 years (ranging from 2 to 40 years). Ten previously reported patients¹¹ are included in this group.

The diagnoses were: nine acute myelogenous leukemia (AML), 16 acute lymphocytic leukemia (ALL), five chronic granulocytic leukemia (CGL), and two multiple myeloma. Table 2 indicates the patients' status at the time of the BMT. All the patients were HLA-A, B, DR identical with their sibling donors. Mixed lymphocyte cultures were bidirectionally negative for all of them. There were seven major blood group incompatibilities. High risk of acute GVHD was expected in ten patients over 30 years of age, in two patients with CGL in acute or accelerated phase, and in four patients with acute leukemia in relapse or subsequent remission. Ten patients exhibited all the criteria of malignant disease with high risk, ie, major chromosome abnormalities in six patients, high WBC count ($\geq 50 \times 10^9/L$) in nine patients, first relapse on therapy in the course of an acute lymphoblastic leukemia (fast disease) in eight patients, and subsequent remission or relapse in four patients. The patients

Fig 1. Bone marrow processing and ex-vivo treatment protocol. Measurements indicate mean ± 1 SD.

were conditioned by fractionated TBI (2 Gy for six fractions for a total dose of 12 Gy) preceding high dose of cyclophosphamide (60 mg per kg body weight × 2). Irradiation was delivered through a linear accelerator with an exposure rate of 5 to 6 cGy per minute. Protocol and consent forms were approved by the institutional review board of the University of Besançon.

Five ALL patients and one AML patient received reinforced chemotherapy in the pre-transplant regimen, according to their high risk of relapse (cytosine arabinoside 100 mg/m² for five days and/or etoposide 100 mg/m² per day for three days). In two patients high dose melphalan (180 mg/m²) was used as a substitute for cyclophosphamide. One multiple myeloma patient was given high-dose melphalan (140 mg/m²) combined with cyclophosphamide preceded by a fractionated TBI.

All but three patients were nursed in closed plastic tent isolators (Isroom, La Calhène, France) with a total nonselective gut decontamination using non absorbable antibiotics. All the patients were given low-dose heparin (1 mg/kg/d) for prophylaxis of veno-occlusive disease of the liver.¹⁷

During the initial feasibility study, posttransplant immunosuppression with methotrexate was maintained until day 100 in four patients and stopped at day 11 post-BMT in six patients (group 1). In 22 patients, no posttransplant immunoprophylaxis was administered (group 2). No maintenance chemotherapy was given following BMT. The median duration of isolation from BMT was 30 days (ranging from 17 to 49 days). Eighteen patients received bone marrow treated with the first MoAb combination (OKT-pool) and 14 with the second (CD-pool). The day of engraftment was defined as the third consecutive day on which the WBC count was $\geq 1.0 \times 10^9/L$. Acute GVHD is defined as beginning <90 days after transplant. Severity was defined according to the Seattle criteria.¹⁸ Genetic markers were available to prove engraftment in 25 patients (sex chromosomes in 12 patients and red blood cell phenotype disparities in 13 patients). No marker was available in seven patients. Chromosome studies were performed by direct processing of the unstimulated bone marrow specimens. An average of 16 mitoses (3 to 110) were analyzed in detail at three, six, and 12 months post-BMT.

Cellular immune function. Immune status was evaluated through surface cell markers by using a panel of seven specific T and B cell MoAbs, lymphocyte proliferative responses to mitogens (PHA, con A) and allogeneic cells (mixed lymphocyte culture). The periods tested were pretransplant and one, three, six, and 12 months posttransplant.

RESULTS

Marrow transplants for the study patients were performed between January 1983 and August 1985.

Early mortality. Of the 32 patients who underwent BMT, eight (five of whom were children) died within three months (mean 35.6 days) due to transplantation-related complications (six had ALL, two had AML). Early toxicity was significantly higher in the patients who had received additional chemotherapy in the preparative regimen (5/8). The causes of death were one fungal septicemia, three interstitial pneumonitis, one acute pancreatitis, one toxoplasmosis, one pseudomonas infection that localized in the neck, and one cardiac and renal failure. The patients who died within 21 days and 40 days post-BMT were not evaluable for engraftment of acute GVHD prevention. Thus 28 patients were evaluated for engraftment and 27 for acute GVHD prevention.

T cell depletion. Processing of the bone marrow led to

*Number of donor cells/number of evaluated cells by X/Y analysis.

the separation of marrow mononuclear cells on Ficoll-Hypaque (Pharmacia, Uppsala, Sweden), which was well adapted to a complement-mediated cytotoxicity. The harvested donor marrow volume was 470 mL $\pm$ 118 and contained a mean of $4.3 \pm 1.9 \times 10^8$ nucleated cells per kilogram recipient weight. These data demonstrate that it is not necessary to aspirate a large volume of bone marrow to harvest sufficient nucleated cells to ensure engraftment. The small volume of collected marrow avoided a perioperative blood transfusion. A density gradient separation of the marrow resulted in a $79\% \pm 16\%$ recovery of committed myeloid progenitors. Treatment with pan-T MoAbs and complement resulted in 1 to 1.5 log of T cell depletion from 30 study marrows out of 32.

The mean T cell depletion was $94\% \pm 4\%$. T cells

harvested with the transplant were $74 \pm 36 \times 10^7$. One round of complement lysis produced an incomplete T cell depletion. A total of $4.7 \pm 3 \times 10^7$ residual viable T cells remained in the inoculum, and the number of viable T cells infused to the patient were $0.99 \pm 0.65 \times 10^6$ per kilogram of the recipient's weight. Although the use of OKT-MoAbs led to a smaller cell clumping than the CD2, -5, and -7 pool, we did not observe a significant difference between the two MoAb combinations in terms of T cell depletion efficacy. The T cell removal with the OKT-pool and the CD-pool was $93\% \pm 6\%$ and $95\% \pm 3\%$ respectively. Committed stem cell assays done before and after complement incubation indicated a $66\% \pm 21\%$ CFU-GM recovery. These data are summarized in Table 3. In most patients the main side effects of the treated marrow infusion were chills and fever.

Table 3. T Cell Counts Before and After Ex-vivo Treatment in HLA-Matched Situation

N* T cells in the transplant $\times 10^7$	= 73.7% $\pm$ 36.1%
N* residual viable T cells $\times 10^7$	= 4.71% $\pm$ 3.27%
% of T cell depletion	= 93.7% $\pm$ 4.08%
1st MoAb association (OKT-pool)	= 93.17% $\pm$ 5.81%
2nd MoAb association (CD-pool)	= 94.85% $\pm$ 2.61%
T cell infused to the patient $\times 10^6/\text{kg}$	= 0.99% $\pm$ 0.65%
CFU-GM recovery post-T cell removal	= 69.2% $\pm$ 17.2%

Engraftment. Engraftment was achieved in all the study patients who received a T cell-depleted transplant. At the time of this analysis (October 15, 1985), no patients had an early (no engraftment within 30 days post-BMT) or a late (graft rejection beyond 90 days post-BMT) graft failure.

The time of recovery to $1 \times 10^9/\text{L}$ white blood cells was 14 to 28 days (mean 18.9 ± 4.7). For 65% of the patients the recovery time was under 20 days. Thirteen to 41 days were needed to recover $0.5 \times 10^9/\text{L}$ granulocytes (mean 20.5 ± 6.4). The time required was under 20 days for 54% of the patients. The time to recover $50 \times 10^9/\text{L}$ platelets was 16 to 65 days (mean 29.2 ± 12.5). The time required was under 30 days for 56% of the patients.

Proof of total chimerism was established in 20 patients by utilizing either genetic markers, eg, sex chromosomes in 11 patients or RBC antigen disparities in 13. Mixed chimerism was documented in two ALL patients grafted in first and second complete remission (CR). One patient relapsed 16 months after BMT; following this he achieved a second remission resulting from the German ALL-BFM-82 chemotherapy protocol.

Acute and chronic GVHD. Twenty-four of the 27 evaluable patients (88%) did not have an acute GVHD higher than grade 0 to 1. No acute GVHD occurred in the first group of ten patients. In group 2, two patients had grade 2 (skin only) confirmed by skin biopsy. Both responded promptly to 2 mg/kg/d of prednisone. A third patient developed a grade 4 GVHD. This patient received more viable T cells than the other patients because of unforeseen technical problems during the in vitro treatment. He was treated with two cycles of bolus intravenous (IV) high-dose methylprednisolone and rabbit antithymocyte globulins. Three months later evidence of extensive chronic GVHD developed in this patient, and he died four months posttransplant.

No other patient developed extensive chronic GVHD. Nevertheless, limited chronic GVHD occurred in four patients (Sicca syndrome in two patients, focal skin lesions in two others). These manifestations promptly disappeared after low-dose prednisolone. In 19 study patients the follow-up was longer than six months.

Chronic GVHD and infectious complications. It is well known that infectious complications that occur after the first three months are seen primarily in patients with a chronic GVHD.¹⁹ A majority of deaths attributed to late infections are reported in patients with active chronic GVHD. Seventeen study patients without extensive disease were analyzed

to evaluate if the clinically significant late infection rate was reduced. Most of them had either none or only one or 2 late infections. Twelve infectious episodes were documented in the 17 study patients (mean: 0.7 ranged between 0 and 3). Skin and genitourinary tract infections and septicemia were the most common types. One impressive example was that of our patient with an active chronic GVHD. He suffered six severe infectious episodes before death occurred.

Relapse. At the time of analysis a medullary leukemia relapse occurred in 13 patients (out of 24 evaluable patients), prior to six months in eight patients and after six months in five. Nine of the 13 were previously defined as "high risk leukemia." In this series the longest period between transplant and relapse was 364 days. Eleven patients have remained in unmaintained continuous CR to date. The mean follow-up is that of 13.3 months (ranging from three to 30 months) with only three patients below six months. The current status of the 32 study patients is reported in Table 4.

Immunologic reconstitution. Recovery of the immune function will be reported at length elsewhere (E. Racadot). In all engrafted patients there was considerable impairment of immunologic status after allogeneic BMT using incomplete T cell-depleted marrow (Fig 2). This severe immune deficiency persisted beyond one year posttransplant. These immune alterations are equivalent to those reported by Zander et al²⁰ after allogeneic BMT using untreated marrow.

DISCUSSION

The removal of T cells by pan-T MoAbs and complement-mediated cytotoxicity is a simple and effective method available in clinical situations. The cytolytic effect of these pan-T MoAbs depends closely on the source of complement and on the anticomplementary effect of bone marrow cells.²¹ Treatment with antibodies and complement in vitro can achieve an efficient and rapid killing of donor T cells. The extent of the removal of T cells can be accurately measured. We did not observe any difference between the two MoAb combinations used in terms of engraftment kinetics and GVHD prevention. The major finding of this study was that a prompt engraftment was achieved in all the patients who had received ex-vivo treated marrow. No early or late graft failure occurred in 17 patients beyond six months after BMT. Our results differ from the clinical data that have been published recently.^{7,10} Martin et al reported 20 patients grafted with marrow treated with a mixture of eight MoAbs and rabbit

Table 4. Current Status of the BMT Program With a T Cell-Depleted Inoculum

complement that led to a 2- to 3-log depletion of T cells. Eight cases of graft failure occurred, seven of them being among the 11 patients prepared for transplantation with 12.0 Gy of TBI, and only one out of the nine patients was prepared with 15.75 Gy.⁷

As part of a European cooperative study on T cell depletion with Campath-1 MoAb (IgM, which fixes human complement and binds both T and B lymphocytes), the incidence of graft failure was high while varying from one team to another (10% to 20%).²² In a prospective randomized controlled trial, clinical data from the UCLA Center showed that five of 20 patients in the CT2/CD2-treated marrow group failed to engraft (none were in the control group).²³ The association of graft failure with a near complete removal of T cells from the donor marrow suggests that T cells in the marrow graft may eliminate host effector cells that survive the conditioning regimen.

Our clinical results on engraftment strongly suggest that our own conditioning regimen protocol may play a major part in the patient's immunologic status. Engraftment depends closely on the magnitude of the residual host-v-graft reactivity caused by residual host T cells, which might react against donor antigens exhibited on donor hematopoietic stem cells.²⁴ Some recent data suggest that increased immunosuppression can overcome the risk of graft failure.⁷

An experimental model is under study in our laboratory in an attempt to demonstrate the influence on the immunologic status of the host at the time of BMT in relation to radiation exposure of the recipient. We would like to emphasize that the patients who received fractionated TBI a week before grafting tolerated the preparative regimen far better.

Evidence shows that acute GVHD can be effectively prevented by a depletion of T cells from the bone marrow. Our own results are in agreement with the recently published results of the Royal Free Hospital,⁵ the Fred Hutchinson Center,⁷ the University of Wisconsin,²⁵ and the Hamman-Smith Hospital.¹⁰ The difference lies at the T cell removal level. A $\geq 99\%$ T cell depletion is reported in most publications, whereas in our experience a mean of 94% T cell depletion has been observed. It could be suggested that a near-to-complete removal does not appear necessary to pre-

vent severe forms of acute GVHD. Nevertheless, we have to interpret our results with caution given the relatively small group of evaluable patients in group 2.

The outlook is even more promising insofar as chronic GVHD is concerned. Extensive chronic GVHD occurred in only one of the 22 study patients followed beyond three months. It is obvious that the late infection rate decreased significantly. To date, we can assume that, independently of its source, a pan-T MoAb cocktail is highly effective in preventing severe forms of acute and chronic GVHD, even in the absence of posttransplant immunoprophylaxis. Other MoAbs in combination with the pan-T MoAb can be used for a T cell depletion, such as antibodies that recognize the CD4 and CD8 T cell molecules.

The suppression of severe forms (grade 3 to 4) of acute GVHD and of extensive forms of chronic GVHD should improve the patient's survival rate in the first year posttransplant, although this fact has not been demonstrated in the present study. Nevertheless, we have to point out that the quality of life is excellent given the low frequency of late infections; the Karnovsky score has always been higher than 90%. We must not, however, overlook the fact that a graft-v-leukemia effect has been closely associated with acute and especially chronic GVHD. Such close correlations were clearly shown when the allograft was done in the course of second remission or later.²⁶ One may therefore expect to find that an improvement in the survival rate is associated with an increase in the relapse rate. However, the clinical series reported by Prentice et al⁵ on a homogeneous group of acute leukemia patients who had undergone a BMT in CR1 did not show that the relapse rate had increased. Nevertheless, we may wonder if a total GVHD prevention in high-risk leukemia is reasonable when the BMT is done in CR2 and subsequent remission. It is hoped that some light will be shed on this question once the randomized clinical trials in progress are completed.

In conclusion, the results of this open pilot study lead us to assume that it has been possible to prevent GVHD successfully through a T cell depletion alone and to obtain engraftment in all the study patients who did not have a late graft failure. Although an evaluation is premature at this stage, the relapse rate appeared to be relatively high in our series. Perhaps there is a close connection with the high percentage of study patients defined as "high risk leukemic."

NOTE ADDED IN PROOF

The authors report two graft rejections and one graft failure in a new series of 14 T-depleted matched BMT since the time of the analysis reported above.

ACKNOWLEDGMENT

We thank Prof G. Santos for reviewing the manuscript and for helpful suggestions. The authors gratefully acknowledge the technical assistance provided by A. Jeanroy and T. Bertrand. They are also indebted to the Besançon BMT nursing teams for the skilled and devoted nursing care given to our patients. C. Delagrèze provided excellent secretarial assistance. Lastly we thank Zinat Saleh for having corrected the English translation of this text.

Chlorpropamide-Induced Pure White Cell Aplasia

By Lee J. Levitt

We investigated the mechanism for isolated agranulocytosis and marrow pure white cell aplasia in an elderly man receiving 0.5 to 1.0 g per day of chlorpropamide (Chl) without other toxic drug exposure or overt systemic illness. Patient marrow revealed an absence of recognizable granulocytic precursors; megakaryocytes and erythroid precursors were normal. The WBC count was 1800/mm³ on admission with only 2% neutrophils; the absolute neutrophil count first exceeded 500/mm³ on the 17th day following cessation of Chl. A serum Chl level on admission was 100µg/mL (acute phase, AP); no Chl was detected in serum (convalescent phase, CP) assessed on the 22nd hospital day. Antineutrophil antibodies were not detected, and T cell depletion failed to augment patient in vitro granulopoiesis. Patient AP serum produced potent complement-mediated inhibition (87% ± 7%) of autologous granulocyte progenitors (CFU-GM) with minimal inhibition of

erythroid (11% ± 5%) or multipotent (5% ± 4%) progenitor cells. Selective inhibition by patient AP serum of CFU-GM (74% ± 11%) was also seen against two allogeneic marrows. Patient CP serum no longer inhibited (6% ± 4%) autologous CFU-GM. Addition of Chl (5 to 120 µg/mL) to CP serum but not to control serum resulted in potent drug concentration-dependent complement-mediated inhibition of autologous and allogeneic CFU-GM. Inhibition of CFU-GM in the presence of Chl was no longer demonstrable following immunoabsorbent removal of IgG from patient serum. Patient serum in the presence of Chl had limited activity against morphologically recognizable marrow granulocytic precursors in a microimmunofluorescence assay. These results are most consistent with the development of Chl-dependent, selective antibody-mediated immune inhibition of granulopoiesis.

© 1987 by Grune & Stratton, Inc.

IMMUNE-MEDIATED drug-dependent destruction of mature neutrophils has been well documented as a cause of agranulocytosis.^{1,2} Development of techniques for the in vitro clonogenic assay of hematopoietic progenitors has also permitted investigation of clinical syndromes associated with immunologic injury to human stem cells.^{3,4} Drug-induced inhibition of human myeloid progenitor growth has been reported in patients with drug-associated neutropenia,^{5,7} and spontaneously arising (non-drug-associated) antibodies directed against granulocyte-macrophage progenitor cells have also recently been described.⁸ The mechanism of drug-dependent suppression of granulopoiesis, however, has not always been clearly elucidated, and the cellular and antigenic specificity of antibodies mediating myeloid stem cell injury have not been well characterized. Failure to demonstrate serum inhibitory activity against autologous granulocyte progenitors in many of these reports also raises questions about the possible alloimmune nature of the antibodies and the pathogenic roles of these inhibitors in the development of neutropenia.

We have previously reported the occurrence of spontaneously arising selective autoantibody-mediated immune inhibition of granulopoiesis in a patient with agranulocytosis

and profound marrow granulocytic hypoplasia (primary pure white cell aplasia).⁸ In this report we investigated the mechanism for acquired neutropenia and marrow pure white cell aplasia in an elderly man receiving high doses of chlorpropamide (Chl) with no other history of toxic drug exposure or overt systemic illness.

CASE REPORT

An 81-year-old man was admitted to the hospital in May 1985 for fever and severe neutropenia. A routine hemogram performed in March 1985 had demonstrated a normal WBC count. The patient was subsequently admitted to Stanford Hospital with fever, otalgia, and neutropenia. He had a prior history of adult onset (Type II) diabetes mellitus treated with dietary restriction and for the last three months had taken 500 to 1,000mg PO daily of Chl. The patient was also taking occasional acetaminophen and oxycodone, and there was no family history of blood dyscrasias. On physical examination he was febrile with a left otitis externa. Phimosis and balanitis were present. The nodes, spleen, and liver were not palpable, and the remainder of the examination was unremarkable. Routine serum chemistries were normal except for a creatinine of 2.7mg/dL. The hematocrit was 35%, the platelets were 486,000/µL, and the WBC count was 1,800/µL with 2% neutrophils, 93% lymphocytes, 3% monocytes, and 2% eosinophils. Direct and indirect (with and without 100µg/mL Chl) Coombs' tests were negative. The reticulocyte count was 1.0%. A bone marrow aspirate and biopsy revealed a mild decrease in overall cellularity (35%). There was virtually a complete absence of granulocytes and all morphologically recognizable myeloid precursors. Erythroid maturation was normal, and megakaryocytes appeared increased in number. No evidence for a thymoma was detected on chest roentgenograms. The patient had a normal serum B₁₂ and folate level and an unremarkable serum immunoelectrophoresis. A serum Chl level obtained on the second hospital day was 100µg/mL (average plasma Chl concentrations following ingestion of 250 mg; range from 19-114 µg/mL, with the variation most dependent upon differences in drug half-life and variations in the volume of distribution). Chlorpropamide was not detectable when the level was again assessed on the 22nd hospital day. The patient was begun on tobramycin and cefoperazone, and his Chl was discontinued. His fever gradually defervesced over the ensuing seven days with a gradual improvement in his balanitis and otitis. The patient's absolute neutrophil count slowly increased and first exceeded 500/µL on the 17th hospital day. A repeat bone

marrow aspirate performed on the 25th hospital day demonstrated reconstitution of marrow myeloid precursors with normal maturation and a myeloid:erythroid (M:E) ratio of approximately 2:1.

METHODS

Assay systems for hematopoietic progenitors. Two to four milliliters of marrow aspirate from normal adult bone donors were drawn into heparinized syringes, layered over Ficoll-Hypaque (Pharmacia, Piscataway, NJ) gradients, and interface mononuclear cells collected. All donors gave fully informed consent prior to marrow aspiration, and all studies were approved by the Stanford University Human Experimentation Committee. Marrow mononuclear cells (5 to $15 \times 10^4/\text{mL}$) were cultured in the presence or absence of 0.5 IU of purified human urinary erythropoietin ($1,140$ U/mg of protein, National Institutes of Health) in triplicate 0.25 -mL aliquots in methylcellulose microwell cultures containing 1% Mo-conditioned medium (MoCM, a medium conditioned by a T lymphoblast cell line containing both myeloid colony-stimulating activity and erythroid burst-promoting activity^{9,10}). Committed erythroid progenitors (burst-forming units-erythroid [BFU-E]) and granulocyte-macrophage progenitors (colony-forming units-granulocyte-macrophage [CFU-GM]), as well as multipotent hematopoietic stem cells (colony-forming units giving rise to mixed colonies containing granulocytic, erythroid, macrophage, and megakaryocytic cells [CFU-GEMM]) were enumerated by in situ observation after 10 to 14 days of incubation at 37°C as previously described.^{8,11} Marrow CFU-GM were also independently assessed in cultures containing 15% human placental conditioned medium, in place of MoCM, as a source of myeloid colony-stimulating activity.¹² In some experiments marrow cells were further fractionated by double-adherence monocyte depletion (less than 2% residual monocytes) and/or solid-phase immunoabsorption with pan-T Leu-1 monoclonal antibody to deplete T lymphocytes (less than 1% to 2% residual marrow T cells) as previously described.¹¹

Cytotoxicity and immunoabsorption studies. Antibody and drug-dependent complement-mediated cytotoxicity against human hematopoietic progenitors was assessed as previously described.⁸ Suspensions of 2×10^6 nonadherent buoyant marrow cells per milliliter were prepared in Iscove's modified Dulbecco's medium. Test serums (patients acute [day 2] and recovery [day 25] serum or control AB serum) were preincubated with saline or diluent controls or varying concentrations of Chl (8 to $120\mu\text{g}/\text{mL}$ final concentration) for 30 minutes at 37°C . Chlorpropamide (Diabinese, Pfizer Pharmaceuticals, New York) was dissolved in either 100% ethanol or in 0.15 mol/L sodium hydroxide with heating and subsequent neutralization with 0.15 mol/L hydrochloric acid; appropriate diluent controls were used in all experiments. One quarter milliliter of the drug-serum mixture was incubated with an equal volume of the marrow cell suspension with or without tested rabbit complement (Pel-Freeze Biological, Rogers, AR) for 30 to 60 minutes at 37°C . After incubation, marrow cells were washed twice, and aliquots were plated in methylcellulose. No decreases in colony formation were noted after cell incubation with complement, control human AB serum, or drug diluent alone at appropriate final concentrations. In some experiments, marrow cells, patient or control serum, drug suspension, and fresh rabbit complement were combined and incubated together at 37°C for 60 minutes prior to washing and plating. In other experiments, drug suspensions were preincubated with marrow cells with or without control sera for 30 minutes at 37°C ; the cells were then washed twice and incubated with test serums with or without a source of fresh complement prior to plating.

Serum antineutrophil activity was independently assessed by a modified granulocyte-microagglutination technique¹³ and by a granulocyte cytotoxicity assay¹⁴ against a panel of granulocytes from ten

normal donors in the presence and in the absence of 20 to $100\mu\text{g}/\text{mL}$ chlorpropamide. Patient antineutrophil activity was also assessed by a Cowan I staphylococcal slide test; the latter includes both direct and indirect tests for detection of cell-bound antibody and allows direct visualization of small numbers of autologous granulocytes during periods of severe granulocytopenia.¹⁵ A fluorochromatic modification of the Terasaki micromethod was used to assay for lymphocyte cytotoxicity against a panel of lymphocytes from 19 normal donors.¹⁶

Patient serum activity against morphologically recognizable marrow granulocytic precursors was assessed via an indirect immunofluorescence technique as previously described⁸; marrow cell pellets were treated with test serum with or without varying concentrations of Chl (20 to $110\mu\text{g}/\text{mL}$ final concentration) or with 80H.5 monoclonal antibody (an IgM complement-fixing murine hybridoma antibody specifically recognizing an antigen on mature granulocytes and on immature marrow myeloid precursor cells¹⁷). Following incubation at 4°C for 20 minutes, cell suspensions were washed with phosphate-buffered saline and were then incubated with either goat antihuman fluorescein isothiocyanate (FITC)-labeled anti-IgG antibody or goat antimouse FITC-labeled anti-IgM antibody (Tago, Burlingame, CA) prior to examination by phase and fluorescence microscopy.

Absorption of IgG from test serums was performed using protein A-sepharose CL-4B affinity chromatography before and after treatment with either rabbit or goat anti-IgG.⁸ Absorbed samples were assessed for adequacy of separation by immunoelectrophoresis; virtually all IgG in the absorbed serums was removed by the immunoabsorbent procedure. Patient's serum was also absorbed with pooled platelets from 14 random donors to remove possible class I (but not class II) anti-HLA alloantibodies as previously described.^{8,18}

RESULTS

Patient marrow obtained on the first and third days of hospitalization was cultured separately in methylcellulose to enumerate marrow multipotential (CFU-GEMM) and committed granulocyte-macrophage (CFU-GM) and erythroid (BFU-E) progenitor cells. Patient colony yield per 2×10^5 buoyant marrow cells included 158 ± 26 (mean $\pm$ SEM) BFU-E, 67 ± 9 CFU-GM, and 4.0 ± 1.8 CFU-GEMM. These results are comparable to those obtained from prior and/or concurrent culture of ten normal human marrows in our laboratory (Table 1). Colony cytologic composition, examined after micropipette selection and histochemical staining, did not differ between patient and control marrows after assessment of individual CFU-GM and CFU-GEMM from each experiment. Independent assessment of patient CFU-GM, using placental-conditioned medium rather than Mo-conditioned medium as a source of myeloid colony-stimulating activity, yielded colony numbers comparable to those obtained after plating of normal human marrow. No increment in patient marrow CFU-GM was seen following marrow T cell depletion by immunoabsorption using a pan-T Leu-1 monoclonal antibody (data not shown). These data together indicate that neither a deficiency of marrow granulocyte-macrophage or multipotent progenitors nor qualitative changes in patient colony cytologic composition could explain the patient's agranulocytosis and marrow white cell aplasia. These results also provide no evidence for autologous T cell inhibition of granulopoiesis.

Table 1. Inhibitory Effect of Patient Acute-Phase Serum on Growth of Autologous Marrow Hematopoietic Progenitors

	Colonies/ 2×10^5 Cells			Percent CFU-GM Inhibition
	CFU-GM	BFU-E	CFU-GEMM	
Control BM*	55 $\pm$ 8	145 $\pm$ 22	3.5 $\pm$ 2.0	—
Patient BM†	67 $\pm$ 9	158 $\pm$ 26	4.0 $\pm$ 2.8	—
Patient BM + AB Serum + C'†	63 $\pm$ 7	143 $\pm$ 19	3.2 $\pm$ 2.0	6
Patient BM + Patient Serum†	59 $\pm$ 81	149 $\pm$ 23	3.0 $\pm$ 1.7	12
Patient BM + Patient Serum + C'†	9 $\pm$ 4	141 $\pm$ 18	3.7 $\pm$ 2.5	87

*Mean $\pm$ SEM from ten separate experiments, each plated in duplicate in methylcellulose cultures.

†Mean $\pm$ SEM from two separate experiments, each plated in triplicate in methylcellulose cultures. Mo-conditioned medium was used as a source of myeloid colony-stimulating activity in both patient and control cultures. Marrow was obtained on two separate occasions during the first five days of hospitalization while the patient was still neutropenic.

BM, bone marrow; C', complement; CFU-GM, colony-forming units for granulocytes and macrophages; BFU-E, burst-forming units-erythroid; CFU-GEMM, colony-forming units for granulocytes, erythroid cells, macrophages, and megakaryocytes.

Patient AP serum was next examined for antineutrophil activity. Both the direct and the indirect Cowan I staphylococcal slide tests performed to detect antineutrophil antibodies were negative. Serum granulocyte cytotoxicity and granulocyte agglutinating activity were assessed against a panel of ten normal donors. Neither the cytotoxicity nor the microagglutination assay detected antineutrophil activity in patient serum. The patient's acute and chronic-phase sera were cytotoxic for lymphocytes derived from only three of 19 normal blood donors.

We next assessed patient AP serum (obtained on the second hospital day) for its effect on autologous marrow hematopoietic progenitors. In two separate experiments using MoCM as a source of myeloid colony-stimulating activity, patient heat-inactivated serum in the presence of complement produced potent (mean 87%) inhibition of autologous marrow CFU-GM with minimal inhibition of either BFU-E or CFU-GEMM (Table 1). Similarly, patient AP serum produced potent complement-mediated inhibition of autologous marrow CFU-GM when patient granulocyte macrophage progenitors were cultured in the presence of placental conditioned medium (Fig 1). The further addition of as much as 120 μ g/mL of Chl to patient AP serum was not associated with any further significant decrement in autologous marrow CFU-GM. Similar selective inhibition of CFU-GM was noted against two separate allogeneic human marrows after treatment with patient serum plus complement (Fig 1). Patient serum did not demonstrate cytotoxicity for lymphocytes derived from either of the two allogeneic marrow donors. Minimal inhibition (12% to 19%) of allogeneic BFU-E or CFU-GEMM was noted after treatment of marrow with patient serum plus complement. Patient serum in the absence of complement had little inhibitory effect on allogeneic hematopoietic progenitors.

The effect of patient acute (day 2, containing 100 μ g/mL Chl) and convalescent (day 25, containing no detectable Chl)-phase serum with and without exogenous Chl was next assessed on growth of autologous marrow CFU-GM. Patient marrow was obtained for this set of experiments upon recovery of the WBC count to 6,800 per μ L, four weeks following cessation of Chl. Previously frozen patient AP serum in the presence of complement again selectively inhibited autologous marrow CFU-GM (Fig 2). However, patient convalescent-phase serum in the presence of complement

failed to inhibit either autologous or allogeneic marrow granulocyte-macrophage progenitors. Patient convalescent-phase serum in the presence of Chl (60 μ g/mL final concentration) did inhibit (79% $\pm$ 21%) autologous CFU-GM (Fig 2). Inhibition of autologous CFU-GM by patient convalescent-phase serum was seen when the previously prepared drug-serum mixture was incubated with marrow plus complement. Inhibition was also noted when marrow, serum, drug suspension, and complement were incubated together simultaneously (88% $\pm$ 26%). Autologous CFU-GM inhibition was not seen, however, when the drug suspension was preincubated with marrow, after which marrow cells were washed and then incubated with serum plus complement prior to plating (11% $\pm$ 7%). No inhibition was noted after marrow cell incubation with AB serum plus 60 μ g/mL Chl plus complement (Fig 2).

Inhibition of patient CFU-GM colony growth by convalescent-phase serum was drug-concentration dependent (Fig 3)

Fig 1. Effects of patient AP serum (containing 110 μ g/mL Chl) with or without exogenous Chl (120 μ g/mL) on growth of autologous and allogeneic granulocyte-macrophage (CFU-GM) progenitor cells. C', complement; D, chlorpropamide. Results expressed as means $\pm$ SEM from two to three separate experiments. Patient acute-phase serum produced potent, C'-mediated inhibition of both autologous and allogeneic marrow CFU-GM. Patient marrow was obtained on days one and three of hospitalization while the patient was still neutropenic.

Fig 2. Effects of patient AP (containing 110 $\mu\text{g}/\text{mL}$) and convalescent-phase (containing no detectable levels of Chl) serum with or without exogenous Chl (60 $\mu\text{g}/\text{mL}$ final concentration) on growth of autologous marrow granulocyte-macrophage (CFU-GM) progenitor cells. C', complement; D, chlorpropamide. Results expressed as means $\pm$ SEM from two separate experiments. Patient convalescent-phase serum inhibited growth of autologous CFU-GM only in the presence of exogenous drug. Marrow was obtained from the patient following recovery of neutropenia.

with demonstrable progenitor inhibition occurring at Chl concentrations of 30 to 120 $\mu\text{g}/\text{mL}$ (the patient's AP serum Chl level on the second hospital day was 100 $\mu\text{g}/\text{mL}$). Patient serum plus Chl in the absence of complement had little demonstrable inhibitory activity against autologous CFU-GM (Fig 3). Patient convalescent-phase serum plus Chl with or without complement had little inhibitory activity against autologous BFU-E.

Absorption studies of patient serum were next performed utilizing protein A-sepharose affinity chromatography to deplete patient serum of IgG immunoglobulin. As demonstrated in Fig 4, inhibition of allogeneic CFU-GM in the presence of 100 $\mu\text{g}/\text{mL}$ Chl could no longer be demonstrated following immunoabsorbent removal of IgG from patient convalescent-phase serum. Absorption of patient's serum with pooled platelets from 14 random donors to remove possible anti-HLA antibody activity did not affect the inhibitory activity of patient convalescent-phase serum plus Chl against allogeneic CFU-GM.

Fig 3. Effects of patient convalescent-phase serum plus varying amounts of exogenous Chl on growth of autologous marrow granulocyte-macrophage (CFU-GM, A) and early erythroid (BFU-E, B) hematopoietic progenitor cells. Marrow was obtained following recovery of neutropenia. C', complement. Results expressed as means $\pm$ SEM from two separate experiments. Patient serum plus drug produced selective drug concentration-dependent inhibition of allogeneic CFU-GM.

Fig 4. Effects of Chl (100 $\mu\text{g}/\text{mL}$ final concentration) plus immunoabsorbed convalescent-phase patient serum on growth of allogeneic granulocyte-macrophage (CFU-GM) progenitor cells. C', complement; D, chlorpropamide. CFU-GM inhibition was no longer demonstrable following protein A immunoabsorbent removal of IgG from patient serum. Pooled platelet immunoabsorption of patient serum to remove possible anti-HLA alloantibodies had no effect on CFU-GM inhibition. Results expressed as means $\pm$ SEM from two to three separate experiments. $\square$, Patient serum; $\square$, patient serum after protein A immunoabsorption; $\square$, patient serum after pooled platelet immunoabsorption.

Patient serum was next assessed for activity against morphologically recognizable marrow myeloid precursors utilizing an indirect immunofluorescent assay. Results were compared with similar assays on the same allogeneic target marrow population using an antihuman IgM monoclonal antibody termed 80H.5. This antibody recognizes an antigen common to mature granulocytes and immature marrow granulocytic cells and was positive by immunofluorescence for 54% $\pm$ 9% of nonadherent allogeneic marrow mononuclear cells. This percentage corresponded to the number of morphologically recognizable granulocytic precursors as assessed by Wright-Giemsa staining of marrow target cell cytocentrifuged preparations. Patient convalescent-phase serum in the presence or absence of 100 $\mu\text{g}/\text{mL}$ Chl was positive for 9% $\pm$ 3% of allogeneic marrow cells ($n = 3$). These results were not different from those obtained after incubation with allogeneic marrow and AB serum with or without Chl (11% $\pm$ 4%). The results suggest that patient serum in the presence or absence of Chl had limited immunofluorescent activity against morphologically recognizable allogeneic marrow granulocytic precursors.

DISCUSSION

This patient's severe neutropenia and marrow pure white cell aplasia completely resolved following discontinuation of Chl and in the absence of immunosuppressive therapy. Patient AP serum (containing 100 $\mu\text{g}/\text{mL}$ Chl) produced potent complement-mediated inhibition of both autologous and allogeneic granulocyte-macrophage (CFU-GM) hematopoietic progenitors with little demonstrable cytotoxic activity against autologous or allogeneic erythroid (BFU-E) and multipotent (CFU-GEMM) progenitors. Patient serum also possessed little activity against autologous and allogeneic lymphocytes, granulocytes, or morphologically identifiable marrow granulocytic precursors. Patient convalescent-phase serum (obtained after recovery of marrow and peripheral

blood granulocytopenia and four weeks following cessation of Chl) no longer inhibited autologous or allogeneic CFU-GM. However, the addition of Chl to patient convalescent-phase serum resulted in potent drug concentration-dependent, complement-mediated selective inhibition of autologous and allogeneic CFU-GM. Inhibition of allogeneic CFU-GM was no longer demonstrable following protein A-sepharose immunoabsorbent removal of IgG from patient serum. These results are most consistent with the development of Chl-dependent selective antibody-mediated immune inhibition of granulopoiesis.

The etiology and pathogenesis of marrow pure white cell aplasia appear in many ways analogous to the previously described syndrome of acquired pure red cell aplasia.^{19,20} Primary chronic pure red cell aplasia has been associated in about 50% of cases with IgG autoantibodies causing either complement-dependent erythroblast lysis, complement-independent inhibition of erythroid progenitor colony growth, or, rarely, inhibition of endogenous circulating erythropoietin.²¹⁻²⁴ We have previously described a patient with pure white cell aplasia associated with a spontaneously arising (non-drug-dependent) complement-fixing IgG autoantibody that selectively inhibited autologous and allogeneic CFU-GM proliferation.⁸ Thymomas have also been reported in association with both acquired pure red cell aplasia and with acquired marrow granulocytic hypoplasia.^{21,25} At least four cases of Chl-associated pure red cell aplasia have been previously reported.²⁶⁻²⁹ Agranulocytosis has also been described as a rare complication of Chl administration; marrow smears in these patients have revealed varying degrees of hypocellularity and only partial preservation of erythroid elements and megakaryocytes.^{30,31} Stein et al have described a female patient with fatal agranulocytosis associated with Chl therapy and the presence of serum leukoagglutinins. The marrow in this case was described as hypocellular with "profound depression of myeloid cells" but with normal erythroid cells and megakaryocytes.³² No further studies were undertaken to evaluate the mechanism of the selective marrow myeloid hypoplasia.

A number of mechanisms have been postulated to explain the pathogenesis of drug-induced immune cytotoxicity.³³ In penicillin-induced hemolytic anemia, the drug is tightly bound to erythrocytes *in vitro* and *in vivo*³⁴; inhibition of autologous CFU-GM was not seen in our patient, however, when Chl was preincubated with target marrow mononuclear cells prior to washing and incubation with patient serum plus complement, thus making a drug-adsorption mechanism unlikely. An "innocent bystander" mechanism has been described in a case of Chl-induced immune hemolytic anemia in which the causal antibody was found to be a complement-requiring IgG immunoglobulin.³⁵ Alternatively, drugs may in some patients lead to the production of "autoantibodies" directed against intrinsic red cell antigens.³³ In this instance, however, antibodies are usually demonstrable in the absence of drug, and cell cytotoxicity usually persists for several weeks to months following cessation of drug therapy.

The explanation regarding cellular specificity of drug-induced immune cytotoxicity remains to be elucidated. Recent

evidence suggests, however, that target cells may have receptors for some drugs or drug-antibody complexes.³⁶ Chlorpromamide-induced immune hemolytic anemia has been described in at least one instance to be associated with an antibody directed against Jk^a antigenic determinants.³⁷ Human red blood cell surface antigenic determinants have not, however, been found on hematopoietic progenitor cells.³⁸ Claas et al have provided evidence that certain drugs may induce autoantibody formation by reacting with restricted non-HLA polymorphic determinants present on the surface of either platelets or granulocytes.³⁹ Cellular specificity in drug-antibody reactions may also be conferred as a consequence of alternative mechanisms of drug-antibody binding to target cell determinants: binding of antidrug antibody to target cells, which occurs only in the presence of drug, has been shown in preliminary experiments utilizing quinidine-dependent antiplatelet antibodies to be mediated by the Fab domain of the antibody rather than the Fc portion of the immunoglobulin.⁴⁰ Our data seem most consistent with the hypothesis that binding of patient drug-antibody complex occurs via an antigenic determinant or receptor that is relatively restricted in expression to the surface of human CFU-GM and which appears to be lost during the early stages of progenitor cell differentiation.⁴¹

Granulocyte-macrophage progenitors, obtained from the patient during a time of profound neutropenia, grew normally in the absence of patient serum or drug. These observations suggest that the assayed colonies may have arisen from primitive precursors that did not bind the patient's drug-antibody complex. Erythroid colonies are often similarly present in normal or increased numbers in the marrow of patients with antibody-mediated inhibition of erythropoiesis and pure red cell aplasia.^{23,42} Marrow colony growth in patients with humoral inhibitors of autologous hematopoiesis has also been described in spontaneously arising pure white cell aplasia and in patients with antibody-mediated aplastic anemia.^{8,43} Normal growth of patient CFU-GM may, alternatively, reflect differences *in vivo* and *in vitro* in the kinetics of drug-antibody receptor binding and cytotoxicity.¹³

Drug-associated inhibition of granulocyte-macrophage progenitor growth has been described infrequently in patients with agranulocytosis.^{5-7,44} Bone marrow smears, however, in a number of these patients have demonstrated coexistent suppression of erythroid and megakaryocytic activity or, alternatively, considerable preservation of myeloid activity with a relative paucity of only the more mature granulocytic elements. In some cases of purported drug-induced suppression of marrow colony formation, the drug inhibited growth of normal allogeneic myeloid colonies but did not suppress growth of patient recovery marrow colonies.^{5,7} Tactile et al have described two patients with diphenylhydantoin-associated antibody-mediated inhibition of granulopoiesis; sera from these patients, however, also appeared capable of mediating destruction of polymorphonuclear leukocytes.⁴⁵ Kelton et al have reported a patient with quinidine-induced pancytopenia and marrow hypoplasia; quinidine plus patient serum inhibited growth of both autologous and allogeneic erythroid and granulocytic progenitor

cells.⁴⁶ Very recently Mamus et al⁴⁷ have described the development of reversible marrow granulocytic aplasia in association with ingestion of ibuprofen. Inhibition of in vitro granulopoiesis in this instance was observed only in the presence of patient serum or IgG plus ibuprofen plus complement.

Further investigations of patients with drug-induced immune suppression of hematopoiesis should provide a better understanding of the mechanisms underlying drug-induced myelosuppression and may identify either surface antigenic determinants or antibodies which would prove useful in the recognition and purification of early hematopoietic progenitor cells.

Altered Plasma Membrane Phospholipid Organization in *Plasmodium falciparum*-Infected Human Erythrocytes

By R.S. Schwartz, J.A. Olson, C. Raventos-Suarez, M. Yee, R.H. Heath, B. Lubin, and R.L. Nagel

The intraerythrocytic development of the malaria parasite is accompanied by distinct morphological and biochemical changes in the host cell membrane, yet little is known about development-related alterations in the transbilayer organization of membrane phospholipids in parasitized cells. This question was examined in human red cells infected with *Plasmodium falciparum*. Normal red cells were infected with strain FCR3 or with clonal derivatives that either produce (K^+) or do not produce (K^-) knobby protuberances on the infected red cells. Parasitized cells were harvested at various stages of parasite development, and the bilayer orientation of red cell membrane phospholipids was determined chemically using 2,4,6-trinitrobenzene sulphonic acid (TNBS) or enzymatically using bee venom phospholipase A_2 (PLA $_2$) and sphingomyelinase C (SMC). We found that parasite development was accompanied by distinct alterations in the red cell membrane transbilayer distribution of phosphatidylcholine (PC), phos-

phatidylethanolamine (PE), and phosphatidylserine (PS). Increases in the exoplasmic membrane leaflet exposure of PE and PS were larger in the late-stage parasitized cells than in the early-stage parasitized cells. Similar results were obtained for PE membrane distribution using either chemical (TNBS) or enzymatic (PLA $_2$ plus SMC) methods, although changes in PS distribution were observed only with TNBS. Uninfected cohort cells derived from mixed populations of infected and uninfected cells exhibited normal patterns of membrane phospholipid organization. The observed alterations in *P. falciparum*-infected red cell membrane phospholipid distribution, which is independent of the presence or absence of knobby protuberances, might be associated with the drastic changes in cell membrane permeability and susceptibility to early hemolysis observed in the late stages of parasite development.

MALARIA IS the world's most common form of hemolytic anemia and remains a major public health problem in many areas of the world. In 1983 the number of malaria cases reported worldwide was 5.5 million,¹ and it is estimated that approximately 65% of the world's population lives in malarious areas.²

Involvement of red cell membrane glycoproteins has been implicated in the attachment of parasites to the membrane,³⁻⁸ and parasite maturation has been shown to result in a redistribution of spectrin,⁹ the major membrane skeletal protein. Alterations in the morphology of the infected cells as well as changes in their osmotic fragility,¹⁰⁻¹³ membrane deformability,^{14,15} and permeability to cations,¹⁶ amino acids,¹⁷ and glucose¹⁷ strongly suggest that membrane lipids are also affected by parasitization.

In normal human erythrocytes, the phospholipids comprising the plasma membrane are distributed asymmetrically between the bilayer leaflets.¹⁸ This asymmetric distribution results in the exoplasmic leaflet being enriched in phosphatidylcholine (PC) and sphingomyelin (SM) while the cytoplasmic leaflet is enriched in phosphatidylethanolamine (PE) and contains all of the phosphatidylserine (PS). Alterations in the bilayer distribution of membrane phospholipids have been noted in several pathologic erythrocytes including sickle cells,¹⁹ spherocytes due to spectrin deficiency,²⁰ elliptocytes due to protein 4.1 deficiency,²¹ as well as in erythrocytes undergoing drug-induced endocytosis.²² We have investigated the organization of membrane phospholipids in human red cells infected with knobby and knobless strains of *Plasmodium falciparum* and determined that significant changes occur in their bilayer distribution during the intracellular maturation of the parasites.

MATERIALS AND METHODS

Cultivation of *P. falciparum*. Parasites were grown at a 5% cell suspension by the method of Jensen and Trager.²³ The FCR3 strain was maintained in synchronous development by a combination of sorbitol treatment²⁴ and gelatin enrichment,²⁵ as proposed by Kile-

jian.²⁶ Sorbitol treatment resulted in cultures highly enriched (>98%) in "early ring" stage-infected cells. Gelatin enrichment resulted in cultures that were predominantly (>75%) late-stage parasites (trophozoites and schizonts). Knobby (A2,K⁺) and knobless (D4,K⁻) clones of FCR3²⁷ were synchronized with sorbitol treatment only. The extent of parasitemia and stage of development was determined by Giemsa-stained cells.

For experiments using the FCR3 strain of *P. falciparum*, fresh, washed normal human red cells were inoculated with late schizonts obtained from gelatin supernatants (parasitemia > 80%) to a final parasitemia of 5% and plated at 1% cell suspension prior to incubation.²⁸ For experiments using the K⁺ or K⁻ clones of FCR3, cultures were first grown at a 1% cell suspension to a parasitemia of >30%. This material was diluted to 5% parasitemia with fresh, washed red cells and plated as for FCR3. For controls, uninfected red cells from the same donor as the infected samples were incubated simultaneously.

Late ring-infected cells were collected from culture approximately 24 hours after inoculation. Trophozoite-infected cells were collected at approximately 36 hours and schizont-infected cells at approximately 48 hours. In some experiments FCR3 trophozoite- or schizont-infected cells were enriched from uninfected red cells by gelatin treatment.²⁵

Determination of erythrocyte plasma membrane phospholipid

organization. Red cell membrane phospholipid organization was determined enzymatically using phospholipase A₂ (PLA₂, from bee venom) and sphingomyelinase C (SMC, from *Staphylococcus aureus*) or chemically using the amino-labeling reagent trinitrobenzene sulphonic acid (TNBS). In the absence of extensive cell hemolysis, these probes do not penetrate the membrane bilayer and react only with those phospholipids exposed on the red cell membrane surface. Therefore, the extent to which the various classes of phospholipids react with these probes is a measure of their exposure in the membrane exoplasmic leaflet.

At various stages of parasite development, 0.1 mL washed packed red cells were treated with 12.5 or 25 units PLA₂ at 37 °C for 45 minutes followed by 1.5 or 3 units SMC for 30 minutes, or with 5 mmol/L TNBS for 1 hour in a total volume of 4 mL (final hematocrit of 2%). The buffer used for the PLA₂/SMC experiments contained 10 mmol/L sodium phosphate, pH 7.4, 10 mmol/L sodium chloride, 0.25 mmol/L magnesium chloride, 0.5 mmol/L calcium chloride, 130 mmol/L potassium chloride and 10 mmol/L glucose; while that used for the TNBS experiments contained 50 mmol/L sodium phosphate, pH 8.5, 1.2 mmol/L potassium phosphate, 120 mmol/L sodium chloride, 5 mmol/L potassium chloride, 0.5% bovine serum albumin, and 5.5 mmol/L glucose. Following the incubation the cells were collected by centrifugation, and the extent at cell hemolysis was determined by the supernatant absorbance of 540 nm. Enzyme-treated cells were immediately lysed with 0.5 mL 5 mmol/L EDTA (pH 7.4), while TNBS-treated cells were washed once in the incubation buffer (pH 7.4), twice in 0.9% saline (pH 7.4), and then lysed with 0.5 mL water. The lipids were extracted, individual phospholipid classes separated by thin-layer chromatography,²⁹ and quantitated by phosphorous determination.³⁰ The percentage of phospholipid hydrolysis (for enzyme-treated cells) or modification (for TNBS-treated cells) was calculated as the ratio of the amount of hydrolysed (modified) phospholipid to the amount of total (hydrolysed or modified + native) phospholipid for each phospholipid species.

Hemoglobin electrophoresis. Aliquots of the red cell lysates prepared from the control or TNBS-treated cells were subjected to hemoglobin electrophoresis on cellulose acetate strips.³¹ Each sample contained the equivalent of from 5 to 10 μ L packed cells; the electrophoresis was performed at pH 8.5 at 380 V for 20 minutes at 24 °C in a Helena Electrophoresis Chamber (Helena Labs, Beaumont, TX). The electrophoresed cellulose acetate strips were stained in Ponceau S stain [0.5% (wt/vol) Ponceau S, 3.5% (wt/vol) sulfosalicylic acid, 3.5% (wt/vol) trichloroacetic acid] and then destained in 5% acetic acid.

RESULTS

Plasma membranes from normal uninfected human erythrocytes maintained in cell culture for periods of time equivalent to those of the *P. falciparum*-infected cells (24 to 48 hours) contained approximately 32% PC, 28% PE, 14% PS, and 25% SM. The total amount of extractable membrane phospholipid in the late-stage parasitized cell populations was about 20% greater than in the uninfected control or early-stage parasitized cells. This increase is likely due to presence of a parasitophorous membrane that encapsulates the parasites and develops during parasite maturation. Membranes from infected cells contained similar proportions of membrane phospholipids, suggesting that parasitization and development of the parasitophorous membrane was not accompanied by conversion of one phospholipid species to another (Table 1). Subjecting normal uninfected erythro-

cytes to phospholipid hydrolysis using PLA₂ and SMC yielded the pattern given in Table 2. Combined PLA₂ and SMC treatments yielded hydrolysis of 75% $\pm$ 3% of the PC, 27% $\pm$ 2% of the PE, none of the PS, and 59% $\pm$ 1% of the SM. In contrast to uninfected cells, *P. falciparum*-infected cells containing early-stage (ring-form) parasites showed a moderate increase in PE hydrolysis (33% $\pm$ 6%, $P < 0.001$) with a concomitant decrease in PC hydrolysis (57% $\pm$ 5%, $P < 0.001$). Hydrolysis of SM (54% $\pm$ 6%) was not significantly different from that of the uninfected cells (59% $\pm$ 1%), nor was there any hydrolysis of PS. Intracellular maturation of the parasites to trophozoites and schizonts resulted in further increases in PE hydrolysis (46% $\pm$ 6%, $P < 0.001$). Infected cells containing clonal derivatives producing knobs (K⁺) also showed marked elevations in PE hydrolysis that progressively increased as the parasites matured from early-stage forms to late-stage forms (34% $\pm$ 8% and 44% $\pm$ 7%, respectively, $P < 0.001$). Similarly, infected cells containing clonal derivatives lacking knobs (K⁻) exhibited increased PE hydrolysis (42% $\pm$ 2% in the late-stage forms, $P < 0.001$, not measured in the early-stage forms). Decreases in the extent of PC hydrolysis were also observed in both the K⁺- and K⁻-infected cells, similar to those seen in the uncloned FCR3-infected cells. Membrane organization of SM was examined only in the early-stage parasitized cells where no differences were observed, nor was there any evidence for PS hydrolysis in any of the infected cells. As noted in Table 1, maturation of the parasites resulted in an approximate 20% increase in total extractable membrane phospholipid.

Although our data indicate that parasitized cell membranes demonstrate a loss of phospholipid asymmetry, we can only speculate on whether such changes represent a complete loss of asymmetry in subpopulations of the infected cells or a partial loss of asymmetry in all of the infected cells. To address this issue we performed calculations using the data given in Table 2 and compared the calculated values to the measured values for phospholipid hydrolysis. For example, considering PE hydrolysis in the synchronous cell culture (Syn)-infected cells, calculations assuming 100% PE hydrolysis (ie, complete loss of PE asymmetry) in all of the parasitized cells yielded an average value of 40% PE hydrolysis. This calculated value compares favorably with the measured value of 46% $\pm$ 6% PE hydrolysis by PLA₂ and SMC in the Syn-late-stage infected cells. Calculations assuming only 50% PE hydrolysis in all of the parasitized cells yielded an average of 31% PE hydrolysis. This calculated value agrees closely with the measured value of 33% $\pm$ 6% PE hydrolysis in the Syn-early-stage infected cells. Similarly, calculations for PE hydrolysis in the K⁺ and K⁻-infected cells yielded an average of 36% PE hydrolysis if all of the PE had translocated to the exoplasmic leaflet and 30% if only 50% of the PE had translocated. These calculated values agree favorably with the measured values of 44% $\pm$ 7% and 34% $\pm$ 8% for K⁺-late- and K⁻-early-stage infected cells, respectively. Thus, our calculations suggest but do not prove, that in early-stage parasitemia only a portion (~50%) of cytoplasmic leaflet PE becomes accessible to the exoplasmic leaflet, whereas in late-stage parasitemia essentially all of

Table 1. Plasma Membrane Phospholipid Content of Human Erythrocytes Infected with *P. falciparum*

Erythrocytes (0.1 mL packed cells, 2% final hematocrit) were incubated for 75 minutes at 37 °C in buffer containing 10 mmol/L sodium phosphate, pH 7.4, 10 mmol/L sodium chloride, 0.25 mmol/L magnesium chloride, 0.5 mmol/L calcium chloride, 130 mmol/L potassium chloride and 10 mmol/L glucose. Following the incubation the cells were collected by centrifugation, and the extent of cell hemolysis was determined from the supernatant absorbance at 540 nm. The cells were then lysed with 0.5 mL 5 mmol/L EDTA, the lipids were extracted, individual phospholipid species separated by thin-layer chromatography and quantitated by phosphorous determination. Erythrocytes infected with *P. falciparum* strain FCR3 were maintained in synchronous cell culture (Syn) as were the cells infected with clonal derivatives that produce (K⁺) or do not produce (K⁻) knobby protuberances. Early stage parasites were predominantly ring forms, while late stage parasites were predominantly trophozoite and schizont forms. Results for total extractable membrane phospholipid (Total PL) are given as µg phosphate/0.1 mL packed cells. Results presented for each phospholipid species represent the percent of total phospholipids, and are the mean (± 1 SD) of from three to eight determinations.

*Significantly different from uninfected normal erythrocytes at $P < 0.05$.

the cytoplasmic leaflet PE becomes accessible to the exoplasmic leaflet.

An alternative method for detecting phospholipids exposed on the surface of cells involves chemically labeling the aminophospholipids using 2,4,6-trinitrobenzene sulphonic acid (TNBS). This reagent only slowly penetrates living cells and has been used by many laboratories to covalently label aminophospholipids exposed on the surface of both normal³²⁻³⁴ and pathologic erythrocytes.³⁴ We obtained similar results using TNBS as we did using phospholipases. As shown in Table 3, uninfected cells maintained in cell culture exhibited labeling of both PE (9% ± 5%) and PS (2% ± 2%). The extent of PE labeling increased dramatically in the parasitized cells; the uncloned FCR3 ring-form parasitized cells showed a threefold increase in PE labeling

($P < 0.001$) that continued to increase as the parasites matured to trophozoites (fivefold increase, $P < 0.001$). Similar increases in PE labeling were also seen in the K⁺ and K⁻ clonal derivatives; however, the extent of increase (two- to threefold, $P < 0.001$) was about 30% less than that seen in the FCR3-infected cells. This may be due to the lower levels of parasitemia achieved in the clonal derivatives or may represent a selective effect of cloning. The extent of PS labeling showed a slightly different pattern from that of PE labeling; none of the early stage parasitized cells showed labeling of PS above uninfected cell values regardless of whether the parasites were of the FCR3, K⁺, or K⁻ variants. However, cells infected with late (trophozoite)-stage parasites showed small but statistically significant increases in PS labeling ($P < 0.05$ for K⁺-trophozoites, $P < 0.003$ for K⁻-tro-

phozoites); this increase was most marked in the schizont-infected cells (fourfold increase, $P < 0.001$). Increases in PE and PS labeling were not associated with any increases in cell hemolysis, which was always < 5%.

It should be noted that our measurements given in Tables 1 to 3 were made using mixtures of both infected and uninfected (cohort) cells. Since < 20% of the cells contained parasites, it is likely that the relatively small changes in phospholipid organization we found for PS in these cell mixtures actually represented much larger changes in the parasitized cells, assuming that cohort cells were unaffected. To address this issue directly we separated cohort cells from parasitized cells by sorbitol treatment²⁴ and examined their membrane phospholipid organization using phospholipases. As shown in Table 4, we found no evidence to indicate that membrane phospholipid organization was abnormal in cohort cells. To minimize hemolysis during cell treatment we used smaller amounts of enzymes in the cohort cell experiments than in the experiments reported in Table 2; therefore, the values obtained for cohort cell membrane phospholipid hydrolysis were somewhat lower.

It is obvious that the validity of using either enzymatic hydrolysis or chemical modification of phospholipids to probe for the exoplasmic leaflet content of phospholipids depends on the reagents being restricted to exoplasmic leaflet phospholipids. Although the extent of cell hemolysis is the

most often used indicator of an intact (and thereby impermeable to the probe) cell membrane, it is certainly not the most accurate method, since even small amounts of penetration by the probes could result in the hydrolysis or modification of cytoplasmic leaflet phospholipids. To more accurately determine the extent of probe penetration in our assay system, we made use of the fact that TNBS covalently labels both phospholipids and proteins containing primary amines. Penetration of intact cells by TNBS would, therefore, result in the labeling of hemoglobin. TNBS-labeled hemoglobin is more negatively charged than is native hemoglobin and can be separated and quantitated by standard hemoglobin electrophoresis techniques. When we analyzed hemolysates prepared from the TNBS-treated cells, we did not find evidence for hemoglobin modification unless the cells were first lysed prior to the addition of TNBS (Fig 1). It can be argued that a TNBS-hemoglobin adduct might not be visible electrophoretically if only a small percentage of the added TNBS actually penetrated the cell membrane. Therefore, to evaluate the sensitivity of our system for detecting TNBS-hemoglobin, we incubated normal uninfected erythrocyte hemolysates (made from a 2% hematocrit) with varying concentrations of TNBS (0 to 5 mmol/L) and examined the electrophoretically separated hemoglobins for the presence of TNBS-hemoglobin. We found that at TNBS concentrations of > 0.25 mmol/L, complete modification of hemoglo-

Table 4. Plasma Membrane Phospholipid Organization of Uninfected Cohort Populations from *P. falciparum*-Infected Human Erythrocytes

Erythrocyte	% Parasitemia	Phospholipid Hydrolysed, % of Total Phospholipids				Total PL
		PC	PE	PS	SM	
Normal erythrocytes maintained in cell culture	0	64 ± 1	14 ± 2	0	26 ± 2	1.7 ± 0.2
Uninfected cohort cells from Syn-late-stage infected mixed cell populations	< 1	72 ± 8	15 ± 1	0	31 ± 7	1.8 ± 0.2

Erythrocytes (0.1 mL packed cells, 2% final hematocrit) were treated with 12.5 units bee venom phospholipase A₂ for 45 minutes at 37 °C followed by 1.5 units *Staphylococcus aureus* sphingomyelinase C for 30 minutes at 37 °C. Uninfected erythrocytes from mixed populations of erythrocytes infected with late-stage forms of strain FCR3 maintained in synchronous cell culture (Syn) were separated by sorbitol treatment. Membrane phospholipids were separated and quantitated as in Table 1. Treatment-induced cell hemolysis was < 3%.

Results for total extractable membrane phospholipid (Total PL) are given as µg phosphate/0.1 mL packed cells.

Values represent the mean (± 1 SD) of four determinations.

Fig 1. Hemoglobin pattern obtained with cellulose acetate electrophoresis. Parasitized cells (2% final hematocrit) were reacted with 5 mmol/L TNBS, as in Table 3, after which the cells were washed three times with saline, hemolysates were made in water, and electrophoresis was performed. Lane 1, erythrocytes infected with trophozoites; lanes 2 to 4, erythrocytes infected with schizonts; lanes 5 to 6, uninfected erythrocytes; lane 7, TNBS-reacted erythrocyte lysate; lane 8, hemoglobin standards (C,S,F,A). Or = Sample application origin.

bin to TNBS-hemoglobin occurred, as evidenced by the complete disappearance of the unmodified hemoglobin band following electrophoresis (Fig 2). Thus, penetration of >5% of TNBS added to our experiments with intact cells (5 mmol/L) would have resulted in the complete modification of hemoglobin to TNBS-hemoglobin. The absence of detectable TNBS-hemoglobin in the TNBS-treated cells strongly suggests that TNBS did not penetrate the cell membrane to any appreciable extent, ie, that only those aminophospholipids located on the exoplasmic bilayer leaflet were labeled.

Fig 2. Hemoglobin pattern obtained with cellulose acetate electrophoresis. Hemolysates prepared from normal uninfected erythrocytes (2% final hematocrit) were reacted at pH 8.5 with TNBS (lane 1, no TNBS; lane 2, 0.05 mmol/L; lane 3, 0.1 mmol/L; lane 4, 0.25 mmol/L; lane 5, 0.5 mmol/L; lane 6, 0.75 mmol/L; lane 7, 1 mmol/L; lane 8, 2 mmol/L; lane 9, 3 mmol/L; lane 10, 4 mmol/L; lane 11, 5 mmol/L) for 1 hour at 37 °C, and then subjected to electrophoresis, as in Fig 1. The presence of TNBS-hemoglobin is indicated by the appearance of a diffuse band that migrates ahead of the unmodified hemoglobin along with the concomitant disappearance of the unmodified hemoglobin. Or = Sample application origin.

DISCUSSION

The evidence presented here suggests that infection and intraerythrocytic maturation of the malaria parasite *Plasmodium falciparum* is associated with profound alterations in the bilayer distribution of phospholipids in the infected host cell membrane. Using two different probes (enzymatic and chemical) to study red cell membrane bilayer phospholipid organization, we found that parasitization resulted in a partial loss of the normal asymmetric organization of membrane phospholipids as evidenced by the appearance of increased amounts of phosphatidylethanolamine (PE) and phosphatidylserine (PS) and a decreased amount of phosphatidylcholine (PC) in the exoplasmic leaflet of infected cells. The extent of these alterations was dependent upon the stage of parasite development; cells infected with early (ring-form) stages showed a partial redistribution of PE and PC but not PS, whereas cells infected with late (trophozoite- and schizont-form) stages also showed the above plus a partial redistribution of PS. Uninfected cohort cells that were cultured along with the infected cells exhibited normal patterns of membrane phospholipid organization. Other workers have similarly reported that cohort cells do not display membrane abnormalities. For example, Sherman and Greenan,³⁵ who examined membrane fluidity in *P. falciparum*-infected human erythrocytes, found no evidence for abnormalities in the uninfected cohort cells.

Redistribution of membrane phospholipids was found to occur in the FCR3 as well as in the knobby (K^+) and knobless (K^-) variants, suggesting that the appearance of knobby protuberances in the infected cells is not associated with specific alterations in the bilayer distribution of membrane phospholipids. Since only the K^+ strain is capable of venous sequestration,³⁶ we conclude that phospholipid redistribution is not involved in the interaction of parasitized cells with endothelium. This conclusion is supported by other workers who have reported that alterations in the phospholipid organization of human erythrocyte membranes does not enhance their adherence to endothelium.³⁷ However, increased exoplasmic leaflet content of aminophospholipids, in particular PS, has been shown to stimulate the adherence of affected red cells to mononuclear phagocytes.³⁸ Whether or not alterations in membrane phospholipid organization in parasitized red cells affect this aspect of the pathophysiology of the disease remains speculative; however, parasitized cells are known to be sequestered in large numbers by the spleen³⁹ and to undergo increased erythrophagocytosis⁴⁰ and adherence to autologous macrophages.¹⁴

Whereas we were able to detect increases in the exoplasmic leaflet content of PE using both the enzymatic (PLA₂ and SMC) and chemical (TNBS) probes, increases in the exoplasmic leaflet content of PS were only apparent using TNBS. Differences in the sensitivity of the probes for phospholipids could be due to the different region of the phospholipid molecule to which each probe reacts; the phospholipases react with the fatty acid-glycerol ester bond that is presumably buried within the hydrophobic core of the bilayer, whereas TNBS labels the aminophospholipid head group that is presumably exposed on the bilayer surface. Similarly, differences in probe sensitivity may be responsible

for the different extents of exoplasmic leaflet PE measured using TNBS and phospholipases in the cultured uninfected erythrocytes.

Other investigators have similarly reported that the plasma membrane of *P falciparum*-infected red cells exhibits abnormal properties, including increases in membrane disordering (fluidity)^{35,41} and a rearrangement of intramembraneous particles.⁴² In this regard, Gupta and Mishra⁴³ reported a redistribution of membrane phospholipids in rhesus monkey red cells infected with *Plasmodium knowlesi*. These authors observed large increases in the exoplasmic leaflet content of PE along with large decreases in the content of PC in that bilayer leaflet. In contrast to our results for *P falciparum*-infected human red cells, *P knowlesi*-infected monkey red cells did not exhibit any alteration in the bilayer distribution of PS. Such differences could be due to differences between monkey and human red cells, species differences between *P knowlesi* and *P falciparum*, or the different intraerythrocytic stages of infection examined (Gupta and Mishra examined only ring-stage-infected cells where we similarly did not find a redistribution of PS). However, the fact that infection of human and monkey red cells by different species of *Plasmodium* both resulted in the bilayer redistribution of membrane phospholipids strongly suggests that phospholipid reorganization may be a common event during the course of the intraerythrocytic maturation of malaria parasites. Alterations in the organization of phospholipids in the parasitized cell membranes could result in many of the observed membrane abnormalities, including

enhanced permeability to cations and nutrients,¹⁷ and may represent a membrane whose integrity is compromised as a result of modifications in membrane lipid-lipid or lipid-protein interactions. This loss of red cell membrane integrity could be a significant component in the early hemolysis of infected cells, a necessary requisite for the continuation of the intraerythrocytic asexual portion of *P falciparum*'s life cycle.

Although we did not specifically examine the mechanism by which phospholipid redistribution occurs in parasitized cells, it is likely to involve alterations in the rate of phospholipid translocation between bilayer leaflets. In this regard the bilayer translocation of PC in normal human erythrocytes is a relatively slow process, whereas the rate is dramatically increased in sickled erythrocytes.⁴⁴ It is also noteworthy that sickle erythrocytes exhibit increased exoplasmic leaflet amounts of PE and PS.^{19,34} Thus an increased interaction of the phospholipid probes with PE and PS may not represent a static increase in the exoplasmic leaflet content of those phospholipids but rather an increased rate at which they are translocated between bilayer leaflets and, hence, become available to interact with the probes.

ACKNOWLEDGMENT

The A2,K⁺ and D4,K⁺ clones of FCR3 were kindly provided by Dr William Trager, and the FCR3 cohort cells were generously provided by Dr Eugene F. Roth, Jr. The authors are grateful to Marion M. Douglass for preparation of this manuscript.

Murine Malaria Decreases Hemopoietic Stem Cells

By Paul H. Silverman, John C. Schooley, and Lynn J. Mahlmann

The causes of anemia and immunosuppression, major outcomes of malaria, are not well established. This study was undertaken to investigate whether erythropoietin (EP) production is adequate and whether the hemopoietic stem cells (CFU-S) were affected during the course of infection. Groups of female Balb/c mice infected with *Plasmodium vinckei vinckei*, *Plasmodium berghei*, or *Plasmodium chabaudi adami* were exposed to five hours of simulated altitude equivalent to 22,000 ft. Plasma samples were collected for EP bioassay and radioimmunoassay (RIA). Using radioiron incorporation as an index of erythropoiesis, differences in response to infection with different species of plasmodia were observed. In general, decreases in erythropoietic activity were observed in bone marrow and

spleen as the infection progressed and continued to be depressed after apparent resolution of a nonlethal infection with *P. chabaudi adami*. Marrow from infected and control femurs were tested for CFU-S content using the spleen colony assay. The cellularity and CFU-S content of the femoral marrow decrease as the parasitemia increases. All three species of plasmodia stimulate EP production during peak parasitemias, indicating that adequate amounts of EP are available to the erythron during malarial infection. Depletion of CFU-S and probable lack of compensatory turnover of CFU-S may contribute to the disease characteristics of malaria.

ANEMIA is a major complication of malaria and contributes to the morbidity and mortality effects of the disease. Numerous studies over the past 20 years have indicated that mechanisms of red cell destruction and autoimmune responses are by themselves inadequate to account for the severity and extent of anemia caused by malaria.¹⁻⁴

Another aspect of malaria infection concomitant with anemia is immunosuppression. Efforts to elucidate these mechanisms have been largely limited to clinical observations and studies that have focused on peripheral blood cells.⁵⁻⁹ These studies have tended to suggest that deficiencies in T lymphocytes occur and that splenic macrophages play a role in regulating immune hyporesponsiveness during malaria infection. Other workers have suggested that immunosuppression is due either to impairment of the progenitor cells of granulocytes/macrophages or an imbalance of the competition between erythropoietic and immune cell lineages, which are all derived from a common pluripotent stem cell (CFU-S).^{10,11}

We¹² and others^{13,14} have observed that during infection with murine malaria, an ample quantity of erythropoietin (EP) is produced; however, erythroid progenitors fail to respond to the hormone. From the data presented here, which expands our previous report,¹² it is apparent that the CFU-S compartment in the bone marrow decreases during the course of infection.

MATERIALS AND METHODS

Female Balb/c and outbred Swiss Webster mice (Bantin and Kingman, Fremont, CA) between 6 and 10 weeks of age were used as indicated in the text. The principles of laboratory animal care as promulgated by the Public Health Service National Institutes of Services were observed. The animals were housed in an American Association for Accreditation of Laboratory Animal Care (AAALAC)-accredited facility.

Three species of murine malaria were used: *Plasmodium vinckei vinckei* (Pvv), *P. berghei* (Pb), and *P. chabaudi adami* (Pca). Normal mice were inoculated by intravenous (IV) injection with 10⁵ infected red blood cells. Parasitemia counts were made from tail blood smears stained with Dif Quik (American Scientific Products, McGraw Park, IL). The percent of infected erythrocytes was determined by examining 200 to 1,000 red blood cells. Multiple infection of red cells with parasites were often observed but were recorded as a single infection.

Infected and uninfected Swiss Webster mice were exposed to five hours in a decompression chamber at a simulated altitude of 22,000 ft (6,706 m Po₂ = 67.1 torr) and then sacrificed. Infected and uninfected mice not exposed to simulated high altitude served as controls. Heparinized whole blood from groups of 12 to 14 mice was collected by cardiac puncture, pooled, and centrifuged. The plasma samples were dialyzed, lyophilized, and reconstituted to the original volumes. Erythropoietin levels were measured by a polycythemic assay^{15,16} and radioimmunoassay (RIA).¹⁷

Groups of six infected and uninfected BALB/c mice were injected IV with 0.5 μ Ci ⁵⁹FeCl₃ (New England Nuclear, Boston; catalogue no. NEZ-037) and sacrificed 6 hours later. The spleens and both femurs from each mouse were counted in a Hewlett Packard gamma well counter (Palo Alto, CA). One group of uninfected mice was injected intraperitoneally (IP) with phenylhydrazine (60 μ g/g) for two consecutive days. Two days after the second injection 0.50 μ Ci ⁵⁹FeCl₃ was given IV.

Recipient Balb/c mice for CFU-S bioassay were irradiated with 700 cGy (100 cGy/min) delivered from a ⁶⁰Co irradiation source just prior to transplantation.¹⁸ At this level of whole body irradiation there is less than 0.1 CFU-S per spleen in each group of ten endogenous irradiation control mice. These controls were routinely a part of the experimental protocol. Single cell suspensions of donor femoral marrow were prepared and injected IV into the recipients. Femoral cellularity was determined using Zap-oglobin II and a Coulter Counter model ZBI (Coulter Electronics, Hialeah, FL). Eight days later whole blood was collected via cardiac puncture for determining parasitemias and xenodiagnosis. Xenodiagnosis was performed by injecting IV 0.20 mL whole blood into normal mice

whenever the parasitemias of the CFU-S assay mice appeared negative. The spleens were placed in Bouins solution, and the number of spleen colonies were counted using a dissecting microscope. Some spleens were processed for histologic examination.

RESULTS

Erythropoietin production. The results summarized in Table 1 indicated that the plasma EP concentrations are normal during the early course of infection with all three species of plasmodia. When parasitemias are high (12% to 40%), EP concentrations increase two- to 100-fold, depending upon the species of *Plasmodium*. An additional challenge of hypoxia produces no additional EP in mice infected with Pb, but mice infected with Pvv or Pca do increase their plasma levels of EP.

Radioiron incorporation. Studies on the erythropoietic activity of the bone marrow and the spleen utilizing radioiron incorporation revealed a substantial increase in marrow and a decrease in the spleen of mice infected with Pvv (Table 2). Mice infected with Pb or Pca showed a dramatic decrease in erythropoiesis in both the marrow and spleen as the infection progressed to acute levels. During the late stages of infection with Pca when the parasitemia was very low or negative, radioiron incorporation was about 85% and 50% of normal in marrow and spleen, respectively (Table 3).

Bone marrow cellularity. Determinations of the total number of nucleated cells in the femora of mice infected with Pvv or Pb indicated consistently that a marked reduction occurs soon after infection (Table 4). The bone marrow cellularity of femora of mice continued to fall as the infection

progressed, dropping to 40% with Pvv and to 60% of normal with Pb shortly before death (Figs 1 and 2) ($P < 0.001$).

The total bone marrow cellularity of femora from mice infected with nonlethal Pca decreased to 60% of normal on days 7 to 9 postinoculation but began to recover several days after the peak parasitemia on day 12 (Fig 3, Table 4). It was observed that femora and other bones from mice in the later stages of murine malaria were brittle. It appeared that osteoclasia was taking place, resulting in thinner bones and an increase in bone marrow volume.

Spleen colony assay. During the process of transplantation of bone marrow cells for spleen colony assays, the possibility of transfer of parasites from infected donors to irradiated recipients was monitored by blood smear examination of the recipients on the day of sacrifice. In the majority of recipients no evidence of parasitemia was observed. In those recipient mice in which parasites were detected, the infection usually was present in trace amounts ($<1:1000$ RBC) and rarely 1% to 5% with Pvv. Histologic examination of spleens from recipient mice that received marrow from control or malaria infected donors revealed no differences in cell types or parenchymal colony distribution. Also, there were no apparent macroscopic differences or significant variations in the number of spleen colonies in individual mice in similar treatment groups with or without low-level malaria infections.

Stem cell changes. Infection with Pvv did not appear to increase the stem cell content in the femora during the early phase of the disease. Death from Pvv infection occurred seven to nine days after inoculation when the stem cell populations were reduced by more than 50% (Fig 1) ($P < 0.001$). During the early phases of infection with Pb, an increase in the CFU-S content of the femora was observed. However, in the late stages of infection with Pb stem cell content dropped to less than 25% of normal just before death of the host (Fig 2).

Pca infection had little or no effect on the stem cell content in the femora until the peripheral blood parasitemia was 15% as observed on day 7. However, the CFU-S per 10^6 nucleated bone marrow cells showed a 20% to 50% increase above normal during the early phase of infection. Maximum depression of the CFU-S content and CFU-S per 10^6 bone marrow cells was observed on day 14, after the peak parasitemia had passed, and there was only a trace amount of the parasites detectable in the peripheral blood. The cellularity and the CFU-S content were at normal levels by day 23, about the time the infection was resolved (Fig 3).

In contrast to the bone marrow data, our assays showed an increase in CFU-S content in the blood and spleens of mice infected with Pca. Normal blood contained about 1.0 CFU-S/0.30 mL. On days 6, 14, and 23, the CFU-S in 0.30 mL was 15, >50 , and 2. The CFU-S content and cellularity of the spleen in uninfected mice contained 2,500 CFU-S and about 170×10^6 cells. On day 14, when the parasitemia was less than 1%, the CFU-S content reached 38,000, and the cellularity rose to 970×10^6 cells. By day 23 postinoculation, when the parasitemia was negative, the CFU-S content dropped to 15,000 and cellularity to 380×10^6 cells.

Changes in the spleen. Splenomegaly has long been recognized as a characteristic response to malaria and other parasitic infections. The spleen in an infected animal increases seven to ten times over normal spleen weights (Table 4). Histologic examination of the spleen during the height of the response indicated that the cellular contents were predominantly granulocytic and lymphocytic with dispersed foci of erythroid elements. No histologic evidence of enhanced splenic erythropoiesis was apparent. The predominant granulocytic and lymphocytic character of the spleen was maintained until death occurred in the mice infected with Pb or Pvv. In mice infected with Pca the cellular character of the spleen began to alter after resolution of the

malaria, eventually returning to normal size and histologic appearances.

DISCUSSION

The data presented here together with the work of others^{13,14} demonstrate that ample amounts of functional erythropoietin are produced during infection with malaria. Indeed, during the later stages of infection with Pb, the EP plasma levels are not further increased by an hypoxic exposure, suggesting that the EP generating system is stimulated maximally (Table 1). Mice infected with Pvv and Pca are capable of responding to an additional hypoxic stimulus at or

near the height of parasitemia. The reasons for the differences between Pvv, Pca, and Pb in the stimulation of EP production require further investigation. In any case, these results suggest that the lack of an adequate erythropoietic response during malaria infection is probably due to a failure of the erythroid progenitor cells to respond to EP, or a decreased production of erythroid progenitors, and/or a diminished production of multipotential stem cells.

The changes in bone marrow content of mice during the course of infection with malaria show striking differences between the three species of parasites used in this study.

Infection with the highly virulent murine malaria, Pvv, led

to high parasitemias, low hematocrits, and death in seven to nine days (Fig 1). Associated with these events is a rapidly declining total femoral cellularity dropping to less than 50% of normal at the time of death. Similarly, the stem cell content showed a parallel decline, dropping to 45% of the normal level before death of the mice.

The temporal pattern of cellular changes in the bone marrow of mice infected with Pb differed from both Pvv and Pca infections. Pb stimulated stem cell populations during the early phase of infection even though total bone marrow cellularity was declining. It is possible that the stimulation of bone marrow stem cells by Pb is related to its propensity for immature erythrocytes and its predilection for recycling in the bone marrow.¹⁹

Pb has a less rapid increase in parasitemia and reaches lower levels of parasitism than does Pvv. On the other hand, Pb eventually kills its host shortly after stem cell populations drop to less than 25% of normal.

A substantial migration of CFU-S from bone marrow to spleen occurs during the early phase of the infection. However, it is apparent from histologic and functional observations that the spleen from an infected animal, enriched with stem cells, does not meet the erythropoietic and hemopoietic needs of the host. The data on six hours uptake of ^{59}Fe by bone marrow and spleen tissue during the course of infection with the three species of plasmodia indicated that the depressed erythropoietic capacity of marrow is paralleled by a similar depression in the spleen. The evidence for decreased erythropoietic capacity in both sites is apparent irrespective of the seven- to tenfold increase in spleen cellularity that is associated with malaria infection. One must conclude that at least during the first days of infection the enlarged spleen does not compensate for the lost erythropoietic capacity of the bone marrow or, probably, other depressed hemopoietic functions. It has been recently reported that the depressed

BMC = Bone marrow cells.

immunologic response in patients during infection and convalescence was associated with a loss of T lymphocytes—both helper and suppressor T cell subsets—from the peripheral blood.²⁰ These findings of a loss of peripheral lymphocytes may result from stem cell depletion and may represent a fundamental contributor to the pathology of malaria.

Early studies on the mechanism of stem cell depletion suggest that a humoral substance is involved. A possible mechanism of action might be due to the effects of tumor necrosis factor (TNF), which is produced by macrophages during the processing of malaria antigen. It has been reported that TNF inhibits adipocyte gene expression.^{21,22} Adipocytes are a major cellular component of the adherent stromal bone marrow and provide an essential environment for renewal and differentiation of the nonadherent hemopoietic stem cells. The inhibitory action of malaria-induced TNF might account for both the drop in total cellularity and the depletion of hemopoietic stem cells.

The effect of a depleted hemopoietic stem cell population is of importance to the outcome of malaria infection. These multipotential stem cells are known to be the source of all blood cells, and their loss might reduce the host's capacity to meet physiologic needs during stress of the disease.

ACKNOWLEDGMENT

We are grateful to Drs A.C. Allison and E.M. Eugui of the Institute of Biological Sciences, Syntex Research, Palo Alto, California for gifts of the plasmodia used in these studies. We thank Dr Gisela Clemons for carrying out the radioimmunoassay for erythropoietin.

Prevention of Platelet Alloimmunization in Dogs With Systemic Cyclosporine and by UV-Irradiation or Cyclosporine-Loading of Donor Platelets

By Sherrill J. Slichter, H. Joachim Deeg, and Michael S. Kennedy

To study the immunosuppressive effects of three different treatments, 30 dogs received at weekly intervals eight platelet transfusions from a single random donor dog. The three experimental protocols were (1) daily oral cyclosporine (Cs) treatment of recipients; (2) in vitro ultraviolet (UV)-irradiation of donor platelets; and (3) Cs-loading of donor platelets. All nine recipients of Cs, 11/12 (92%) recipients of UV-irradiated platelets, and 5/9 (56%) recipients of Cs-loaded donor platelets remained nonimmunized to repeated transfusions of donor platelets. In contrast, only 3 of 21 untreated controls (14%) were not alloimmunized by donor platelets. Moreover, 44% to 67% of the nonimmunized recipients remained tolerant to continued

platelet transfusions from their original donor even after experimental therapy was discontinued. Forty-three percent to 100% of transfusions from secondary donors were also accepted without causing alloimmunization, suggesting that tolerance induced by prior treatment was not specific for the primary donor. However, survival of both the original and secondary donor platelets was reduced to about half the starting level, suggesting that some immune response to platelets had occurred. Also, recipients immunized by their original donor's platelets frequently developed refractoriness to platelets from other donors.

© 1987 by Grune & Stratton, Inc.

TO PREVENT or modify the immune response to transplanted tissue, a number of immunosuppressive treatments have been developed, such as irradiation, chemotherapeutic regimens, polyclonal or monoclonal antibodies, and the use of cyclosporine (Cs).¹

A more recent approach is the modification of donor cells or tissues. Certain antigen-presenting cells such as macrophages or dendritic cells are now known to be necessary for the donor's tissue to be recognized by the recipient. Thus, several attempts have been made to eliminate or inactivate these cells.²⁻⁴ Reportedly, successful inactivation has been achieved by maintaining long-term cell or tissue cultures in a high concentration of oxygen,⁵ by using monoclonal antibodies (MoAbs) directed at Class II antigens (expressed on antigen-presenting cells),⁶ and by exposing donor cells or tissue to ultraviolet (UV) light in the intermediate wavelength spectrum.^{3,7,8}

Although there is substantial information on the value of these and other agents in organ transplantation, little is known about their ability to prevent immune recognition of repeatedly transfused cells. In particular, we are concerned about alloimmunization to transfused platelets, since it represents a major problem in the management of thrombocytopenic patients. Studies suggest that 40% to 100% of repeatedly transfused patients become alloimmunized, often after only a few transfusions.^{9,10} We have previously used a dog platelet transfusion model to evaluate methods of pre-

venting platelet alloimmunization¹¹ (and unpublished data). This report describes further studies using this model to evaluate recipient treatment with Cs and UV-exposure or Cs-loading of donor platelets as methods of preventing platelet alloimmunization.

METHODS

Selection of Donor and Recipient Dogs

The dogs used for these experiments were of various breeds and of either sex. Dogs were vaccinated (DHL and parvo virus) and quarantined for one to two months to exclude any diseases. In addition, two or three autologous ⁵¹Cr-labeled platelet survival measurements (see below) were performed on each recipient dog to ensure baseline normal platelet kinetics before donor transfusions were initiated.

During the course of the study, eight different dogs were used as donors for the 30 platelet transfusion recipients. All of the donors and most of the recipients were typed for serologically determined dog histocompatibility antigens (DLA-A and B).¹² In all instances tested, donors and recipients were incompatible for one or more DLA-antigens. In addition, for some studies mixed lymphocyte cultures were performed with cells obtained from donors and from recipients both pre- and posttransfusion.¹³ In all tested donor-recipient pairs, cells showed reciprocal stimulation both before and after the donor transfusions and experimental therapy.

Survival of Radiochromium(⁵¹Cr)-Labeled Platelets

Platelets were prepared from the donor dog and labeled with radiochromium as previously described.¹⁴ Every week 50 mL of blood was drawn from each donor for each recipient into 7.5 mL of acid-citrate-dextrose (ACD). A platelet concentrate was prepared by differential centrifugation and labeled with 300 μ Ci of ⁵¹Cr. After infusion of these platelets, blood samples (3 mL blood drawn into 0.1 mL potassium EDTA) were obtained at one hour, twice on the second day, and once daily during the third and fourth days. Survival was calculated by least squares computerized-fitting of the radioactivity in the blood samples.^{15,16} Autologous platelet survival in 56 normal dogs averaged 5.1 ± 0.9 days (mean $\pm$ 1 SD).

Platelet recovery was calculated as follows by extending the survival curve to time zero (T0):

$$\text{Recovery (\%)} = \frac{\text{Radioactivity at T0} \times \text{blood vol (estimated at 80 mL/kg)}}{\text{Total radioactivity of injected platelets}} \times 100$$

Autologous recovery in normal dogs was $51\% \pm 12\%$ (mean ± 1 SD) of the injected platelets.

Alloimmunization was defined as a decrease in the recovery of labeled donor platelets to $<5\%$ at 24 hours posttransfusion. One additional donor transfusion was given after the development of alloimmunization to confirm the accuracy of the end point. Thus, two serial donor platelet transfusions showing poor survivals were required to categorize a recipient as alloimmunized.

Alloimmunization of Untreated Dogs

Control values for induction of alloimmunization were determined by transfusing 21 recipient dogs with platelets from one of 11 donors. Twenty of 21 (95%) became immunized after an average of 3.1 ± 0.7 (range one to 12) transfusions¹¹ (Fig 1). As 18/21 (86%) of these recipient controls were immunized by eight or fewer transfusions, an eight-week transfusion schedule was selected for the subsequent alloimmunization studies, ie, the treated dogs received platelets from their donor until alloimmunization developed or a maximum of eight transfusions had been given.

Treatment Programs

Systemic cyclosporine. Cyclosporine (Cs, Sandoz, Basel, Switzerland) was emulsified in corn oil¹⁷ and administered orally in doses of 15 mg/kg/d. Treatment was started on the day of the first platelet transfusion and continued for up to eight weeks or until alloimmunization occurred. To document absorption of drug and maintenance of adequate levels, Cs serum levels were monitored in two recipient dogs throughout their treatment using a radioimmunoassay (RIA), as previously described.¹⁸ Serum drug levels were obtained every three to five days as trough levels just before the next daily dose. For one dog the average trough levels were 105 ± 68 (range 22 to 255) ng/mL and for the second dog 139 ± 30 (range 108 to 192) ng/mL. Therapeutic Cs drug levels are considered to range between 100 to 400 ng/mL.

UV-exposed platelets. After radiochromium labeling, platelets were resuspended in a volume of 6 to 10 mL of Ringer's-citrate-dextrose (RCD) and placed (to a depth of 1.5 mm) in an open Petri dish and continuously agitated on a shaker platform during UV exposure. UV irradiation was delivered by a mineral light lamp (UVP, San Gabriel, CA) providing wavelengths between 220 to 290 nm. The dose delivered was determined by using a Black-Ray Ultra-violet Meter (Model J225, UVP) with a maximum sensitivity at 254 nm. After UV exposure the contents of the Petri dish were aspirated into a syringe for injection.

Fig 1. Prevention of platelet alloimmunization. Shown are the percentages of recipients who did not become immunized by eight platelet transfusions from a single unrelated donor while on treatment followed by eight transfusions from the same donor while off therapy. Data in treated dogs are compared to results in untreated control dogs. At the end of each transfusion sequence, the number of dogs not immunized to donor platelets is given as a fraction of the number of dogs studied. The treatment programs were (1) oral Cs given to the recipient; (2) UV irradiation of platelets; and (3) Cs loading of platelets.

Cyclosporine-loaded platelets. Radiochromium-labeled donor platelets, resuspended in 4.6 mL of RCD, were incubated for 1 hour at 22 °C with 55 µg/mL of Cs prepared by adding 0.25 mg (5 µL of a 50 mg/mL solution) of Cs in ethanol: Cremaphor (intravenous [IV] solution from Sandoz) to the platelets. Following incubation the platelets were injected IV, the recipients receiving only 0.25 mg of Cs per injection. Blood taken immediately and one hour after injection contained no measurable Cs.

Uptake of Cs was assessed by measuring the platelet Cs content by high-pressure liquid chromatography and by using radiolabeled ³H-cyclosporine provided by Dr Eric Wiskott of Sandoz. The amount of Cs incorporated was 6% to 12% of that added. There was no difference in Cs uptake in donor platelets between dogs who subsequently became immunized and those who did not.

Further Transfusion Studies

Any recipient not immunized by eight transfusions while receiving the experimental treatment was given an additional eight transfusions from the same donor while off treatment or until immunization developed, whichever occurred first. When the transfusion schedule from the original donor was completed, the recipient dogs then received transfusions from one to three additional donors (referred to as secondary donors) while off experimental treatment. Transfusions were provided from the randomly selected secondary DLA-incompatible donors until immunization developed or until a maximum of eight transfusions were given.

Statistical Analysis

Mean values of experimental and control groups were compared by Student's *t* test.¹⁹

RESULTS

Autologous Platelet Transfusions

Recovery and survival measurements with experimental treatment. To ensure that treatment did not adversely affect the viability of transfused platelets, autologous platelet recovery and survival measurements were performed for each experimental treatment. Four dogs were given oral Cs during the transfusion of radiolabeled autologous platelets. Recoveries and survivals with this treatment were not significantly different from those in 56 untreated controls ($P > 0.10$) (Table 1).

Doses of UV irradiation given to autologous platelets were 200, 400, or 600 µW/cm² for one minute (total doses of 12, 24, and 36 mJ/cm², respectively). These doses did not affect autologous platelet survival (Table 1). However, in two dogs

Table 1. Recovery and Survival of ⁵¹Cr-Labeled Autologous Platelets

Treatment	Number of Dogs Tested	Platelet	
		Recovery (%)*	Survival (Days)*
None	56	51 $\pm$ 12	5.1 $\pm$ 0.9
Systemic Cs	4	58 $\pm$ 9	4.1 $\pm$ 0.6
UV-exposed platelets	14	52 $\pm$ 6	4.3 $\pm$ 1.1
Cs-loaded platelets	5	57 $\pm$ 6	4.9 $\pm$ 1.3

*Given as the mean ± 1 SD.

By Student's *t* test, none of the treatment programs produced platelet recovery and survival measurements that were statistically different from untreated controls.

that received $600 \mu\text{W}/\text{cm}^2$ for ten minutes (total dose of $360 \text{ mJ}/\text{cm}^2$), there was no recovery or survival of autologous platelets (data not shown). Cyclosporine-loading in five dogs did not reduce platelet viability (Table 1).

Allogeneic Platelet Transfusions

Recipient treatment with oral cyclosporine. Of the nine recipients who received oral Cs therapy, none became immunized after eight transfusions from a single random donor (Fig 1). These results were significantly different from those in the 21 untreated control dogs ($P < 0.001$); only three of them (14%) remained unimmunized after eight transfusions. Furthermore, 6/9 recipients (67%) were still responsive to transfused platelets when Cs was stopped, even after eight additional transfusions from the same donor ($P < 0.001$, compared to controls). The other three recipients became immunized after four, five, and six additional donor transfusions given off treatment (Fig 1).

Although zero time-recovery values for the original donor's platelets in the nonimmunized recipients were within the normal range throughout the 16 transfusions (eight on and eight off treatment), donor platelet survivals were only 2.2 ± 0.5 days, ie, about half normal (Fig 2).

UV exposure of donor platelets. Overall, 11/12 recipients (92%) of UV-exposed donor platelets (12 to $36 \text{ mJ}/\text{cm}^2$) were protected from alloimmunization. These UV-exposed donor platelets produced a significantly lower rate of alloimmunization than unmodified platelets given to control recipients ($P < 0.001$) (Fig 1).

To determine if an effective dose of UV irradiation could be achieved through a blood bag, platelets from two donors were individually irradiated through a piece of plastic cut from a Fenwall platelet storage bag (PL 732, Fenwall Laboratories, Deerfield, IL) that was laid over the Petri dish containing the platelets. (As the UV penetrance through the plastic bag was poor with the available UV source, a maximum dose of $100 \mu\text{W}/\text{cm}^2$ could be obtained.) However, by irradiating at $100 \mu\text{W}/\text{cm}^2$ for four minutes, the equivalent

of our standard dose of $400 \mu\text{W}/\text{cm}^2$ for one minute was achieved, ie, the total UV dose given to platelets by each of these exposures was $24 \text{ mJ}/\text{cm}^2$. Two recipients received donor platelets irradiated through the plastic and, as controls, two others received the same donor's platelets given the exact exposure ($100 \mu\text{W}/\text{cm}^2$ for four minutes) without interposition of plastic; all four recipients were protected from alloimmunization (data included above).

When transfusions from the original platelet donor were continued off treatment, three recipients became immunized after one, two, and five transfusions, respectively (Fig 1). Thus, 8/12 recipients (67%) were not immunized by a total of 16 transfusions, eight on and eight off treatment ($P < 0.001$ compared to controls).

The eight nonimmunized recipients were given platelets from two or three other donors until immunization occurred or a maximum of eight transfusions from each of these other donors had been given. Prior treatment prevented alloimmunization to platelets from 10/23 (43%) of the secondary donors tested (Table 2). However, compatible donors were found for only four (50%) of the nonimmunized recipients. After completion of these secondary donor transfusion studies, six of the nonimmunized recipients were transfused with platelets from their original donor and two (33%) were immunized.

Three of the four immunized recipients were each given platelets from one or two other donors; only 1/5 of the secondary donors' platelets (20%) remained compatible during eight transfusions (Table 2).

Recovery of UV-exposed donor platelets in the nonimmunized recipients was normal, but survival was reduced (Fig 3). However, the survival of donor platelets off treatment (3.1 ± 0.4 days) was somewhat better than on treatment (2.5 ± 0.3 days). Recoveries from the secondary donors in the nonimmunized recipients averaged $42\% \pm 10\%$, and survivals were 2.9 ± 1.3 days.

Cyclosporine-loaded donor platelets. Undesirable side effects of systemic Cs are sometimes observed in immunosuppressed patients. We therefore evaluated the use of in vitro Cs-loaded donor platelets for preventing alloimmunization. Five of 9 (56%) of the recipients of Cs-loaded platelets did not become alloimmunized (Fig 1) ($P < 0.05$ compared to untreated controls). Furthermore, 4/9 or 44% remained nonimmunized to the original donor's platelets even off treatment ($P < 0.001$). In addition, none of the three nonimmunized recipients tested were alloimmunized after receiving untreated platelets from either of two secondary donors (Table 2).

In contrast to the data in the nonimmunized recipients, all three tested recipients who had become immunized to their original donors' platelets also were alloimmunized after receiving fewer than eight transfusions of unmodified platelets from five secondary donors (Table 2).

Recoveries of the original donor's platelets in the recipients were within the normal range for both the treated and untreated transfusions while survivals were reduced (Fig 4). Recovery of the secondary donor's platelets averaged $51\% \pm 14\%$ in the nonimmunized recipients and survival was 3.0 ± 1.0 days.

Fig 2. Viability of platelets in nonimmunized Cs-treated recipients. The upper part of the figure shows the mean recovery (± 1 SD) of donor platelets in the recipient on treatment (closed circles) and off treatment (open circles). The normal range (± 1 SD) for dog platelet recovery in 56 normal animals is shown as the hatched area. The lower panel shows the mean survival (± 1 SD) of donor platelets in recipients on treatment (closed circles) and off treatment (open circles). The number of recipient animals who were not immunized by each transfusion is shown below each survival. The range of normal platelet survival (± 1 SD) in dogs is shown as the hatched area.

Table 2. Response to Platelets From Secondary Donors

Treatment Given to Original Donor's Platelets	Refractory Recipients*		Nonrefractory Recipients*	
	Number of Recipients Tested	No. Nonrefractory Secondary Donors/No. Tested (%)†	Number of Recipients Tested	No. Nonrefractory Secondary Donors/No. Tested (%)†
UV-exposed platelets	3	1/5 (20%)	8	10/23 (43%)
Cs-loaded platelets	3	0/5 (0%)	3	6/6 (100%)

*In each treatment group, recipients refractory as well as nonrefractory to their original donor's platelets were transfused with platelets from other donors, referred to as secondary donors, while off treatment (see text).

†The number of secondary donors to whom the recipients did not become refractory with eight transfusions is given compared to the number of secondary donors transfused.

DISCUSSION

Specific attempts to prevent platelet alloimmunization in chronically transfused thrombocytopenic patients, other than by using single donor platelets^{20,21} or leukocyte-free blood products,^{22,23} have not been reported. Our studies have shown that both immunosuppression with systemic Cs and UV irradiation of donor platelets were almost uniformly successful (100% and 92%, respectively) in preventing alloimmunization to eight weekly platelet transfusions from a single random donor. These results are much better than the nonimmunized rate of only 14% in untreated controls ($P < 0.001$ for both treatments). Furthermore, almost two thirds of the nonimmunized previously treated recipients remained unimmunized after eight additional transfusions from the same donor, suggesting the induction of a tolerant state. To determine if this tolerance was specific for the original donor's platelets, platelets from other random donors were transfused without treatment of the recipient or the donor's platelets. The number of Cs-treated recipients evaluated for such specificity was too small to permit a firm conclusion (data not given). However, among the recipients tolerant to eight UV-treated and eight nontreated platelet transfusions from their original donor, platelets from 43% of the secondary donors tested were also compatible. In addition, there was some evidence that maintenance of this quasitolerant state required continuous transfusions of the

presumed tolerizing antigen; interruption of the transfusion program for a period of months resulted in immunization by untreated transfusions from the primary donor in at least one third of the recipients tested. Similar observations have been made in other models of tolerance.²⁴

We were concerned about the substantial immunosuppressive effects of Cs on human subjects as well as its toxicity to liver and kidneys.²⁵ Therefore, in analogy to the use of vinblastine-loaded platelets in patients with autoimmune thrombocytopenic purpura,²⁶ we evaluated the ability of Cs-loaded donor platelets to prevent immunization. Although 56% of the recipients were apparently unable to recognize Cs-loaded donor platelets, this treatment was inferior to that obtained with either systemic Cs or UV-irradiated donor platelets ($P < 0.001$). However, treatment with Cs-loaded donor platelets was very successful in inducing a state of tolerance not only to untreated platelets of the original donor but also to secondary donors.

In summary, our studies show that some treatment programs that prevent the rejection of organ allografts were successful in reducing the recognition of repeatedly transfused donor platelets in a canine transfusion model. Furthermore, to some extent, these treatments induced a state of "nonspecific tolerance" that persisted even after discontinuation of experimental therapy. However, maintenance of the tolerant state apparently required continuous exposure to the tolerizing antigen. Conversely, in those recipients who

Fig 3. Viability of UV-exposed platelets in nonimmunized recipients. The upper part of the figure shows the mean recovery (± 1 SD) of donor platelets. Transfusions given after UV exposure (on treatment) are shown as closed circles and normal transfusions (off treatment) as open circles. The normal range (± 1 SD) for dog platelet recovery in 56 normal animals is shown as the hatched area. The lower panel shows the mean survival (± 1 SD) of donor platelets after UV exposure (closed circles) and without UV exposure (off treatment, open circles). The number of recipient animals who were not immunized by each transfusion is shown below each survival. The range of normal platelet survival (± 1 SD) in dogs is shown as the hatched area.

Fig 4. Viability of Cs-loaded platelets in nonimmunized recipients. The upper part of the figure shows the mean recovery (± 1 SD) of donor platelets. Transfusions with Cs-loaded donor platelets are shown as closed circles and with normal platelets (off treatment) as open circles. The normal range for dog platelet recovery in 56 normal animals is shown as the hatched area. The lower panel shows the mean survival of Cs-loaded donor platelets (closed circles) and off treatment (open circles). The number of recipient animals who were not immunized by each transfusion is shown below each survival. The range of normal platelet survival in dogs is shown as the hatched area.

became immunized by the original donor's platelets either on or off therapy, alloimmunization usually also developed in response to untreated platelets from other donors.

We also found that the survival of allogeneic donor platelets in every treatment program was consistently reduced as compared to similarly treated autologous platelets. Therefore, we conclude that some degree of alloimmunization to donor platelets probably occurred in recipients who were by definition considered to be nonimmunized. However, as autologous platelet survivals on treatment were only performed on one occasion, we cannot exclude the possibility that there was some cumulative effect of the treatment on donor platelet survival measurements. The recovery of platelets from both the original and secondary donors in the nonimmunized recipients was not compromised, and platelet survival remained about half normal; therefore, useful transfusion support was achieved by this approach. Furthermore, previous studies using *in vitro* platelet aggregation tests, have shown that human platelets maintain normal function after UV exposure²⁷ or Cs loading.²⁸ Although the applicability of our results to man has not been tested, we believe these studies provide a sufficient basis to consider human experiments.

Expression of Two Natural Killer Cell Antigens, H-25 and H-366, by Human Immature Myeloid Cells and by Erythroid and Granulocytic/Monocytic Colony-Forming Units

By David Wisniewski, Robert Knowles, Maria Wachter, Annabel Strife, and Bayard Clarkson

Two monoclonal antibodies (MoAbs), H-25 and H-366, shown previously to react with human peripheral blood large granular lymphocytes with natural killer (NK) cell activity and some peripheral blood monocytes, have now been shown to also react with a significant proportion of the myeloid and erythroid precursor cells in human bone marrow and peripheral blood. In FACS IV cell sorting and immune rosetting of bone marrow cells, the antigens recognized by H-25 and H-366 were found to be expressed on most blasts and promyelocytes but sequentially fewer of the more mature cells of the myeloid lineage. Both antigens were also found on most monocytes but only a minor proportion of lymphoid and nucleated red cells in the bone marrow. In vitro assays detecting hematopoietic colony-forming units revealed that these antigens are expressed by virtually all mature erythroid colony-forming units (day-7 CFU-E), and the majority of the more primitive

erythroid burst forming units (day-14 BFU-E). H-25 but not H-366 was also found on a variable proportion of the day-7 and day-14 granulocytic/monocytic colony-forming units (CFU-GM) in the bone marrow. The same type of precursor cells are also found in the H-25 and H-366 positive cell populations isolated from peripheral blood. In preliminary testing of cells from acute leukemic patients, FACS analysis showed that both antigens are also expressed on leukemic cells from patients with T cell acute lymphocytic leukemia and with myeloid leukemias. These studies demonstrate that the H-25 and H-366 positive NK cells in the peripheral blood retain some of the cell surface properties of early hematopoietic precursor cells, thus providing further evidence supporting the bone marrow origin of NK cells.

IN VITRO semisolid culture techniques have facilitated numerous studies on the regulation of hematopoiesis at the progenitor cell level. While it is clear from these studies¹⁻³ that proliferation and differentiation of hematopoietic progenitor cells are mediated by accessory cell factors and humoral factors, further understanding of the molecular mechanisms involved requires the purification of progenitor cells as well as the regulatory factors acting on them.

Recently our laboratory has been pursuing the purification of hematopoietic progenitor cells and has described a negative selection method for substantially enriching CFU-GM and BFU-E from normal human peripheral blood.^{4,5} Using this method, B lymphocytes, monocytes, and certain high affinity Fc receptor-bearing cells are depleted from mononuclear cells by immunoadherence to plastic plates coated with rabbit antihuman IgG. Cells not attached to these plates are subsequently depleted of T lymphocytes by coating with the pan-T murine monoclonal antibody LyT-3 before their removal by immunoadherence to plastic plates coated with goat antimouse IgG. The final "null" cell fraction is highly enriched for CFU-GM and BFU-E.

More recently, in attempts to further purify these progenitor cells, we sought to remove contaminating natural killer (NK) cells (non-T, non-B cells that display spontaneous cytotoxic activity against a variety of normal, neoplastic, or virus-infected cells⁶) from the null cell fraction using two previously described NK cell reactive monoclonal antibodies.⁷ Both of these antibodies, designated H-25 and H-366, have previously been shown to react with peripheral blood NK cells and monocytes but do not react with Leu-1 positive T lymphocytes, B lymphocytes, granulocytes, red blood cells, or platelets.

Preliminary immunoadherence experiments with the null cell fraction after reaction with these monoclonal antibodies (MoAbs) suggested, however, that antibody H-25 was cross-reactive with CFU-GM and BFU-E, while antibody H-366 was crossreactive with BFU-E. These preliminary observations prompted us to examine in more detail the expression of

antigens detected by H-25 and H-366 by hematopoietic progenitor cells from both normal bone marrow and peripheral blood. Thus, H-25 and H-366 antigen positive (+) and negative (-) cell fractions were obtained by FACS IV sorting and immune rosetting methods. Cell fractions were examined morphologically and also assayed for erythroid and granulocytic/monocytic colony-forming units using well established in vitro semisolid culture techniques. In addition, cells from some fresh acute leukemic samples as well as some established human cell lines were examined for H-25 and H-366 antigen expression by FACS. The results of these studies are the subject of the present report.

MATERIALS AND METHODS

Monoclonal antibodies. Production and characterization of monoclonal antibodies (MoAbs) H-25 and H-366 have been previously described in detail.⁷ Briefly, spleen cells from Balb/c mice immunized with the T cell acute lymphocytic cell line HSB-2 were fused with the P3 NS-1/1-ag 4-1 myeloma cell line by the method of Kohler and Milstein. Two hybrid clones (H-25 and H-366) were found to produce antibodies that bound to the parent HSB-2 cells

but not to human B cell lines. Both hybrids were subsequently passaged as ascites tumors in pristane primed Balb/c mice.

Further characterization of both antibodies revealed similar tissue distribution. Thus, H-25 and H-366 were found in indirect immunofluorescence assays to react with a subset of peripheral blood mononuclear cells (MNC) that have the morphological characteristics of large granular lymphocytes (LGLs) and, furthermore, that contain most of the NK and K cell activity. Both antibodies were also found to react with a variable number of peripheral blood monocytes, a significant proportion of thymocytes (obtained from infant thymuses), but neither antibody was reactive with Leu-1 + T lymphocytes, B lymphocytes, granulocytes, red blood cells, or platelets. In a radioimmune trace-binding assay, H-25 and H-366 were found to react with all T cell lines tested and with the monocytic cell line U937 but weakly or not at all with cell lines of B, myeloid, or erythroid origin. Antibodies H-25 and H-366, which are IgG₁ and IgG_{2b} subclass specific, respectively, immunoprecipitate two polypeptide chains of apparent molecular weights of 96 and 53 kilodaltons from surface labeled HSB-2 cells, H-25 bringing down the former band and H-366 the latter.

In some of the experiments described below, MoAbs MO-1, MY-4, MY-8, N901, B-1 (kindly supplied as ascitic fluids by Dr James Griffin, Harvard Medical School, Cambridge, MA), Leu-1, Leu-4 (kindly provided as culture supernatants by Dr Robert Evans, Sloan-Kettering Institute, New York), and Leu-7 (Becton Dickinson, Mountain View, CA) were used. The production and characterization of these MoAbs have been previously described in detail. Anti-MO-1, which recognizes an antigenic determinant associated with the CR3 receptor, is found on monocytes, granulocytes, and approximately 80% of NK cells.⁸ B-1 identifies a 35,000 molecular weight antigen found specifically on cells of B lineage.⁹ MY-4 and MY-8 antigens are expressed by monocytes, and MY-8 is additionally expressed by cells of the granulocytic series.¹⁰ Leu-1 and Leu-4 are pan-T cell antigens.^{11,12} Anti-N901 detects an antigen, present at low density, on all NK cells and no other subpopulation of peripheral blood cells.¹³ Anti-Leu-7 is an LGL specific antibody that reacts with approximately 50% to 90% of NK cells.¹⁴

Source of cells. Heparinized, venous human peripheral blood (50 to 100 mL) was obtained from healthy volunteers. Human posterior iliac-crest bone marrow was obtained from normal volunteers by aspiration into preservative-free, heparin-containing syringes. Peripheral blood (10 to 20 mL) was additionally collected from these donors as a source of autologous serum. Written, informed consent was always given by the donors.

Human acute leukemia cells. Cells were obtained from the bone marrow and peripheral blood of seven patients with acute myelogenous leukemia (AML), two patients with T cell acute lymphocytic leukemia (T-ALL), and two patients with pre-B Calla⁺ (common acute lymphoblastic leukemia antigen) acute lymphoblastic leukemia (pre-B, ALL). Standard clinical, morphological, and cytochemical criteria were used to establish the diagnosis in each case, and the diagnosis was confirmed by surface marker analysis using a panel of MoAbs. AML patients were subclassified according to the FAB (French-American-British) classification system as AML (M2), acute myeloblastic leukemia with maturation (three patients); APL (M3), acute promyelocytic leukemia (two patients); AMOL (M5A), acute monocytic leukemia without maturation (one patient); and AMOL (M5B), acute monocytic leukemia with maturation (one patient).

Cell lines. Established human cell lines were grown in RPMI 1640 (GIBCO, Grand Island, NY) containing 15% fetal calf serum (FCS) (Hy-Clone, Logan, UT) and 1% penicillin-streptomycin-neomycin (PSN). Their origins are listed in Table 1.

Cell preparation from normal bone marrow and peripheral blood. Normal bone marrow cells were harvested after centrifuga-

tion of the aspirates at 1,000 RPM for ten minutes and suspended in McCoy's 5A modified medium (GIBCO) containing 10% fetal calf serum (FCS) (hereafter referred to as complete medium). Platelets were removed from the cell suspension by centrifugation on a Percoll (Pharmacia, Piscataway, NJ) density solution ($d = 1.050\text{g/mL}$) for 20 minutes at 2,000 RPM. At this density platelets remain at the interface while all nucleated cells are pelleted. After washing the pelleted cells once and resuspending in complete medium, light-density bone marrow cells were obtained by centrifugation over Ficoll-Hypaque (Pharmacia, $d = 1.077\text{g/mL}$). Light-density cells, harvested at the interface, were washed twice, resuspended in complete medium, and incubated (37°C , 5% CO_2) in plastic plates for one hour to remove adherent cells. The resulting light-density, nonadherent bone marrow cells were washed once, resuspended in McCoy's 5A medium containing 10% autologous serum (to minimize Fc receptor binding of antibodies in the immunofluorescence and immune rosetting procedures described below), and kept on ice until further use.

Peripheral blood MNC were obtained by centrifugation of diluted blood over Ficoll-Hypaque. After collecting the interface cells and washing twice, the majority of monocytes were depleted by adherence to plastic plates as described above. Nonadherent cells were collected, washed once, resuspended in McCoy's 5A medium containing 10% autologous plasma, and kept on ice.

Preparation of leukemic cells. Leukemic bone marrow and peripheral blood samples were diluted with complete medium and centrifuged over Percoll ($d = 1.050\text{g/mL}$) to remove platelets. Light-density cells, which were then obtained by Ficoll-Hypaque, were washed twice, resuspended in McCoy's 5A medium containing 10% autologous plasma, and kept on ice until further use. Cytospin preparations of the light-density cells were prepared in a Shandon-Elliot cytospin and stained with May-Grunwald-Giemsa, and differential counts were performed on 500 cells. Greater than 85% of the light-density cells were blasts in all acute leukemic samples studied.

Cell separation by FACS IV. Normal bone marrow and peripheral blood nonadherent, light-density cells (15 to 30×10^6), obtained as described, were incubated with previously determined saturating amounts of different monoclonal antibodies for 30 minutes on ice. Control cells (which were used to determine background fluorescence) were incubated with purified mouse IgG (containing all subclasses, Coulter Immunology, Hialeah, FL) except in those experiments where antibody Leu-7 (isotype IgM) was used, in which case control cells were incubated with purified mouse IgM (Coulter). After washing twice the cells were stained with fluorescein isothiocyanate (FITC)-conjugated F(ab')_2 fragments of goat antimouse IgG (Cappel, Malvern, PA) or a purified FITC-labeled antibody against total mouse immunoglobulins (Coulter) when Leu-7 was the incubating antibody. After labeling, the cells were washed twice, resuspended in McCoy's 5A medium containing 5% FCS and 25mmol/L Hepes buffer, and kept on ice, away from light, until FACS IV analysis. Following analysis cells were sorted under sterile conditions into antigen positive (fluorescent cells above control background cells) and negative cell fractions. In some experiments an intermediate fraction consisting of weakly positive staining cells was also collected. To facilitate the separation of antigen positive and negative cells, fluorescence analysis and sorting were performed on a logarithmic scale. Sorted cell fractions were washed twice and resuspended in complete medium for functional analyses (described below) and cytocentrifuge smears.

Cell separation by immune rosetting. Normal bone marrow and peripheral blood light-density, nonadherent cells were incubated with different MoAbs as described above. After washing twice, the cells were resuspended in McCoy's 5A medium containing 10% autologous serum (or plasma) to a cell concentration of 15×10^6 cells/mL and mixed with 1 mL of a 2% solution of bovine red blood

Table 1. Expression of H-25 and H-366 Antigens by Human Cell Lines

Cell Lines	Cell Type	Reference	% Reactivity*	
			H-25	H-366
HSB-2	T Cell lymphoblastic	15	98	98
U937	Monocytic	16	97	96
KG-1	Myeloblastic	17	73	25
HL-60	Promyelocytic	18	80	0
SK-DHL-2	B Cell Lymphoma (CALLA ⁺)	19	31	0
SK-BU-1-Bt(8;14)-1	B Cell Lymphoma (CALLA ⁺)	20	29	0
SK-BU-1-BN-1	EBV-transformed B cell (CALLA ⁻)	20	0	0
SK-CML7-BN-1	EBV-transformed B cell (CALLA ⁻)	21	0	0
SK-CML-7-Bt(9;22)-33†	EBV-transformed B cell (CALLA ⁻)	21	0	0

*Cell lines were reacted with antibodies H-25 and H-366 separately, stained with FITC-conjugated F(ab')₂ fragments of goat antimouse IgG, and analyzed by FACS.

†SK-CML-7-Bt(9;22)-33 contains the 9q;22q translocation (Philadelphia "PH" chromosome). CALLA = Common acute lymphoblastic leukemia antigen. EBV = Epstein-Barr virus.

cells (Hazleton, Denver, PA) coated with affinity purified goat antimouse IgG (Boehringer Mannheim, Indianapolis, IN) by CrCL₃ linkage.²² After centrifugation the tubes were placed on ice for 30 minutes, at which time the pelleted cells were resuspended and rosetted, and nonrosetted cells were separated by centrifugation on a Percoll density solution ($d = 1.080\text{g/mL}$). Nonrosetted cells recovered at the interface and rosetted cells from the pellet (after lysis of indicator bovine RBCs with Tris buffered NH₄Cl) were washed twice and resuspended in complete medium. Efficiency of the immune rosette technique was tested by FACS IV analysis of the nonrosetting cell fractions from peripheral blood. In all cases less than 2% contamination of antigen positive cells were found in the nonrosetting cell fractions regardless of the MoAb used.

Immunofluorescence (FACS IV) analysis of cells from human leukemic samples and cell lines. Light-density cells obtained from the bone marrow and/or peripheral blood of fresh acute leukemic samples as well as established human cell lines were analyzed for H-25 and H-366 antigen expression by indirect immunofluorescence (FACS IV) as described above. The percentage of "positive" cells was calculated by a computer procedure that subtracts the control (background) fluorescence from that of the experimental sample.

Identification of peripheral blood monocytes. Monocytes were identified in the peripheral blood cell fractions obtained by FACS IV sorting and immune rosetting by morphological and histochemical (alpha-naphthyl acetate esterase staining kit, Sigma, St. Louis) analysis of cytocentrifuge smears. The percentage of esterase positive cells was determined by counting 500 cells under oil immersion microscopy.

Progenitor cell assays. Nonadherent, light-density unseparated cells from normal bone marrow and peripheral blood as well as the cell fractions obtained by sorting and immune rosetting were cultured essentially as previously described.⁵ Briefly, for CFU-E and BFU-E, cell cultures consisted of 1 mL of Iscove's modified Dulbecco's medium (IMDM, GIBCO) containing 25% FCS, 0.8% deionized bovine serum albumin, 10% Mo-T cell line-conditioned medium,^{23,24} 10^{-4}M 2-mercaptoethanol, 1 unit of partially purified human urinary erythropoietin (Ep, Toyobo, New York), and methylcellulose at a final concentration of 1.3%. Triplicate cultures were incubated in a humidified atmosphere of 5% CO₂ in air. Day 7 aggregates consisting of greater than eight cells of unequivocally red color were counted as 1 CFU-E. Day 14 red cell aggregates of greater than 50 cells were scored as 1 BFU-E. Peripheral blood erythroid colonies were counted on day 14 only.

The granulocytic/monocytic colony-forming unit (CFU-GM) assay was done exactly as described above for CFU-E and BFU-E,

except that erythropoietin was replaced by an equal volume of IMDM. Aggregates consisting of greater than eight cells were counted on days 7 and 14. Peripheral blood CFU-GM were enumerated on day 14 only. All colony counts were done using an inverted microscope at magnification of 125X.

Calculation of percentage recovery of colonies for each cell fraction obtained by FACS IV and immune rosetting. Total colony recovery for a given type was determined by summing the colonies recovered in each fraction. The number of colonies recovered in each fraction was then expressed as a percentage of the total colonies recovered.

RESULTS

Expression of antigens H-25 and H-366 by normal peripheral blood large granular lymphocytes (LGLs). In three preliminary experiments using the method of indirect immune rosetting, LGLs (where NK cells are known to reside²⁵) were obtained from normal peripheral blood nonadherent MNC by simultaneous immune rosette depletion of T lymphocytes, B lymphocytes, and residual monocytes after reaction with monoclonal antibodies Leu-1, Leu-4, B-1, MY-4, and MY-8. The resulting nonrosetting cell population when examined morphologically consisted predominantly of cells with a slightly indented nucleus and abundant cytoplasm containing azurophilic granules (morphological characteristics ascribed to LGLs²⁵) with <5% alpha-naphthyl acetate esterase positive cells. Figure 1 shows representative FACS IV immunofluorescence profiles of the LGL-enriched cell population obtained after reaction with MoAbs H-25 and H-366 and for comparative purposes with N901, MO-1, and Leu-7, which are also known to react with the majority of LGLs. It can be seen that both H-25 and H-366 antigens are expressed by the LGL-enriched population, although H-25 antigen density is more heterogeneous and considerably higher than H-366 on a substantial number of LGLs. In comparison to N901, H-25 and H-366 antigen densities were considerably higher on many of these cells, while the expression of antigen MO-1 appeared similar to H-366. Leu-7 antigen, like H-25, also displayed broad heterogeneity; however, in contrast to antigens H-25, H-366, MO-1, and N901, which were expressed by approximately 85% of the LGL-enriched population, Leu-7 antigen was expressed by approximately 50%.

Fig 1. Expression of antigens H-25 and H-366 by LGLs and comparison with antigens N901, MO-1, and Leu-7. LGLs were obtained from peripheral blood by negative selection whereby T lymphocytes, B lymphocytes, and residual monocytes were simultaneously depleted from nonadherent MNC by indirect immune rosetting using MoAbs Leu-1, Leu-4, B-1, MY-4, and MY-8. FACS IV histograms shown here were obtained by indirect immunofluorescence staining after reacting LGLs with each indicated MoAb separately and analyzing 10,000 cells. Background fluorescence staining (control) was obtained by incubating cells with purified mouse IgG (containing all subclasses) or purified mouse IgM (when Leu-7 was the incubating antibody). Note that the number of cells in the LGL enriched cell population reacting with MoAbs B-1, Leu-1, and Leu-4 was $<2\%$, indicating that B and T lymphocytes were efficiently depleted by the immune rosette technique.

FACS IV analysis and sorting of normal bone marrow cells using MoAbs H-25 and H-366. Figure 2 shows representative FACS IV immunofluorescence profiles, before and after sorting, of nonadherent, light-density normal bone marrow cells after reaction with MoAbs H-25 (eight experiments) and H-366 (six experiments). Before sorting, it could be seen that there was a small proportion of bone marrow cells that were positive over background for both antibodies, H-25 being much more pronounced than H-366. Since there was no distinct peak of antigen positive cells for either antibody, a window of cells between 30 to 50 channels (representing an average of 29% and 11% of the H-25 and H-366 antibody-treated cells, respectively) was routinely discarded to minimize overlap between antigen positive and antigen negative cells. In eight experiments,

before sorting, there was a mean of $15\% (\pm 11\%)$ H-25⁺ and $7\% (\pm 2\%)$ H-366⁺ cells. After sorting, FACS IV re-analysis of the H-25⁺ and H-366⁺ cell fractions showed a mean purity of $>85\%$, while H-25 and H-366 cell fractions were always $>98\%$ pure.

Morphology of H-25 positive and H-366 positive bone marrow cells. Differential counts obtained from May-Grunwald-Giemsa-stained cytocentrifuge smears of H-25⁺, H-25⁻, H-366⁺, and H-366⁻ sorted cell fractions are given in Table 2 along with the percent recovery of each of the cell types listed. Blasts, promyelocytes, and monocytes were significantly enriched in the H-25⁺ cell fraction. Based on the total number of cells recovered (sum of the H-25⁺ and H-25⁻ cell fractions), a mean of $76\% (\pm 18\%)$, $88\% (\pm 17\%)$, and $92\% (\pm 16\%)$ of the blasts, promyelocytes, and monocytes respectively were recovered in the H-25⁺ cell fraction. Of the total number of myelocytes, metamyelocytes, and bands (and neutrophils) recovered, $26\% (\pm 31\%)$, $17\% (\pm 33\%)$, and $14\% (\pm 29\%)$ respectively were found in the H-25⁺ cell fraction. These results suggest that antigen H-25 is more strongly expressed by blasts and promyelocytes and sequentially diminishes through myeloid maturation beyond the promyelocyte stage. H-25⁺ cells also included minor proportions of lymphoid (mean = $13\% \pm 6\%$) and nucleated red cells (mean = $18\% \pm 15\%$). Similarly, blasts, promyelocytes, and monocytes were enriched in the H-366⁺ cell fraction; however, the percent recoveries of these three cell types ($54\% \pm 20\%$, $36\% \pm 36\%$, $67\% \pm 27\%$) were lower than that found in the H-25⁺ cell fraction. In contrast to the H-25⁺ cell fraction, essentially all of the myelocytes, metamyelocytes, bands, and neutrophils recovered from sorting with antibody H-366 were found in the H-366⁻ cell fraction. Similar to H-25⁺ cells, H-366⁺ cells also included small numbers of lymphoid (mean = $11\% \pm 5\%$) and nucleated red cells (mean = $26\% \pm 23\%$).

Expression of H-25 and H-366 antigens by hematopoietic progenitor cells from normal bone marrow and peripheral blood. H-25⁺, H-25⁻, H-366⁺, and H-366⁻ sorted bone marrow cell fractions were assayed for erythroid and granulocytic colony-forming units and the results are given in Table 3. For antibody H-25 in the bone marrow of eight individuals tested, a significant but widely variable proportion of day 7 ($39\% \pm 28\%$) and day 14 ($67\% \pm 37\%$) CFU-GM were sorted into the H-25⁺ cell fraction. In contrast, a mean of $99\% (\pm 0.7\%)$ of the CFU-E and $86\% (\pm 17\%)$ of the BFU-E were found in the H-25⁺ cell fraction, suggesting that the expression of antigen H-25 is higher on erythroid progenitor cells (particularly CFU-E) than on granulocytic/monocytic progenitor cells. It should also be noted that while the percent recoveries of CFU-E and BFU-E were similar to the average total cell recovery (43%) in the sorting experiments with antibody H-25, recoveries of day 7 and day 14 CFU-GM were generally about 65% of the expected value.

For antibody H-366 in the bone marrow of six individuals tested, a mean of $97\% (\pm 3\%)$ of the CFU-E and $46\% (\pm 20\%)$ of the BFU-E were sorted into the H-366⁺ cell fraction. In contrast, essentially all of the day 7 and day 14 CFU-GM were found in the H-366⁻ cell fraction, suggesting that the

Fig 2. FACS IV analysis of expression of antigens H-25 and H-366 by normal bone marrow cells. Nonadherent, light-density bone marrow cells were separately reacted with MoAbs H-25 and H-366 and separated into H-25⁺ and H-25⁻ and H-366⁺ and H-366⁻ cell fractions using the FACS IV cell sorter (Becton Dickinson). Results are expressed as FACS histograms on a log fluorescence scale with 10,000 cells analyzed. Reanalysis of the sorted cells showed that the purity of the H-25⁻ and H-366⁻ cell fractions were >98% pure, while the H-25⁺ and H-366⁺ cell fractions were >85% pure. Cells from each fraction were then analyzed for morphology and colony assays (see Tables 2 and 3).

expression of antigen H-366, similar to antigen H-25, is relatively high on CFU-E and a significant number of BFU-E but in contrast to H-25 is significantly lower or not expressed by either day 7 or day 14 CFU-GM. The average recoveries of all four types of progenitor cells in the sorting experiments with antibody H-366 were similar to the average total cell recovery (54%).

For comparative purposes, MoAbs Mo-1 and Leu-7 were also reacted with normal bone marrow cells, sorted into Mo-1⁺, Mo-1⁻, Leu-7⁺, and Leu-7⁻ cell fractions and assayed for hematopoietic progenitor cells. The results, also given in Table 3, show that antigens Mo-1 and Leu-7 are not expressed by either erythroid or granulocytic/monocytic

colony-forming units. It should also be noted that, in contrast to the morphological cell profiles seen in the H-25⁺ and H-366⁺ cell fractions (Table 2), neither the Leu-7⁺ nor the Mo-1⁺ cell fractions were enriched for blasts or promyelocytes. Rather, Leu-7⁺ cells consisted of >90% lymphoid-appearing cells, while Mo-1⁺ cells contained >90% mature myeloid cells (myelocytes → neutrophils).

As stated above, a wide variability of day 7 and day 14 CFU-GM were found in the H-25⁺ sorted cell fractions, suggesting that the expression of antigen H-25 on CFU-GM is low. To test this, three experiments were done whereby bone marrow cells were reacted with antibody H-25 and sorted into antigen negative (-), weakly positive (+/-) and

positive (+) cell fractions. Figure 3 shows representative FACS IV profiles before and after sorting. Cell differentials and the results of progenitor cells assays done on the various cell fractions are given in Table 4 and Fig 4 respectively. Again it is seen that the majority of blasts and promyelocytes were sorted into the H-25⁺ cell fraction along with minor percentages of myelocytes, metamyelocytes, bands, and neutrophils. In contrast, the H-25 (+/-) cell fraction contained minor proportions of blasts and promyelocytes, while substantial numbers of myelocytes, metamyelocytes, bands, and neutrophils were recovered in this fraction. These results again suggest that the expression of antigen H-25 by myeloid cells is inversely related to the state of maturation and therefore is more highly expressed on the more immature blasts and promyelocytes. For the progenitor cell assays an average of 58% ($\pm$ 10%) of day 7 and 53% ($\pm$ 15%) of day 14 CFU-GM were recovered in the H-25 (+/-) cell fraction with lower proportions of both types of granulocytic progenitor cells being found in the H-25⁺ and H-25⁻ cell fractions. In contrast, virtually all the CFU-E were in the H-25⁺ cell fraction, and the great majority of BFU-E also expressed the H-25 antigen (69% $\pm$ 7% were in the H-25⁺ cell fraction and 23% $\pm$ 5% in the H-25 (+/-) cell fraction). These results again suggest that the expression of antigen H-25 by erythroid progenitor cells is high, while the expression by the majority of day 7 and day 14 CFU-GM is relatively low.

Normal peripheral blood CFU-GM and BFU-E, both of which are generally considered to be more primitive than the majority of bone marrow erythroid and granulocytic/mono-

cytic colony-forming units^{26,27} were also examined for the expression of antigens H-25 and H-366. For three separate sorting experiments (results shown in Fig 5), a mean of 86% ($\pm$ 5%) and 39% ($\pm$ 13%) of peripheral blood BFU-E and CFU-GM respectively, were recovered in the H-25⁺ cell fraction while 39% ($\pm$ 22%) of the BFU-E and only 3% ($\pm$ 3%) of the CFU-GM were sorted into the H-366⁺ cell fraction. Thus, the number of peripheral blood CFU-GM and BFU-E that express antigens H-25 and H-366 appears similar to the number found on normal bone marrow BFU-E and 14-day CFU-GM.

Morphological and alpha-naphthyl acetate esterase analysis of the sorted peripheral blood cell fractions showed that both H-25⁺ and H-366⁺ cells consisted predominantly of LGLs and a small number of contaminating monocytes (<9%), while H-25⁻ and H-366⁻ cells were composed of typical small- and medium-sized lymphocytes and <1% monocytes.

The results obtained in the FACS IV experiments were confirmed by studies using the method of immune rosetting to separate normal bone marrow and peripheral blood. Thus, for three separate bone marrow experiments (Fig 6), a mean of 99% ($\pm$ 2%) of the CFU-E and 83% ($\pm$ 20%) of the BFU-E were found in the H-25⁺ immune-rosetted cell fraction, while an average of 39% ($\pm$ 27%) and 77% ($\pm$ 21%) of day-7 and day-14 CFU-GM respectively were recovered in this fraction. For antibody H-366, 96% ($\pm$ 7%), 68% ($\pm$ 41%), 5% ($\pm$ 2%), and 25% ($\pm$ 6%) of the CFU-E, BFU-E, day-7 and day-14 CFU-GM respectively were recovered in the H-366⁺

Fig 3. Expression of H-25 antigen by normal bone marrow cells. Nonadherent, light-density bone marrow cells were reacted with H-25 MoAb and separated into the 13% most brightly fluorescent H-25 positive cells (H-25⁺), 27% of the least fluorescent H-25 positive cells (H-25^{+/−}), and H-25 negative (H-25[−]) cell fractions. After sorting, 10,000 cells from each fraction were re-analyzed, and the results here are expressed as FACS histograms. Cell fractions were then analyzed for morphology and colony assays (see Table 4 and Fig 4 respectively).

immune-rosetted cell fraction. For peripheral blood ($n = 3$, Fig 7), 94% ($\pm 3\%$) of the BFU-E and 74% ($\pm 14\%$) of the CFU-GM were found in the H-25⁺ cell fraction while 42% ($\pm 23\%$) and 6% ($\pm 2\%$) of the BFU-E and CFU-GM respectively were H-366⁺. Thus the results obtained by immune rosetting were similar to the FACS IV results with the

Fig 4. Separation of bone marrow hematopoietic colony-forming cells using MoAb H-25 and FACS IV. Nonadherent, light-density bone marrow cells after reacting with antibody H-25 were separated into H-25 (+), H-25 (+/−), and H-25 (−) cell fractions by FACS IV (see Table 4) and the fractions assayed for hematopoietic colony-forming units. For three separate experiments, H-25 (+) cells were selected as the 13% ($\pm 7\%$) most brightly fluorescent cells, while H-25 (+/−) cells included the 27% ($\pm 10\%$) least fluorescent cells. Bars and vertical lines represent the mean (± 1 SD) of the total number of colonies recovered after sorting. The number of colonies per 5×10^4 unseparated nucleated bone marrow cells were 80 ± 16 CFU-E, 33 ± 20 BFU-E, 179 ± 40 day-7 CFU-GM, and 35 ± 11 day-14 CFU-GM.

exception that a considerably higher number of bone marrow day-14 CFU-GM were found to be H-366⁺ by immune rosetting. Figures 6 and 7 also show that MoAbs Mo-1 and B-1, which served as controls in the immune rosetting experiments, do not react with either normal bone marrow or peripheral blood hematopoietic colony-forming units.

Expression of antigens H-25 and H-366 on acute leukemic cells. In light of the FACS IV and immune rosetting studies with normal bone marrow showing that antigens H-25 and H-366 are expressed by a substantial number of immature myeloid cells, it was of interest to examine the expression of these antigens on fresh leukemic cells. As shown in Table 5, the blast cells from all patients with AML studied were H-25⁺ and H-366⁺, antigen H-25 generally being expressed by a higher number of these blasts. It should be noted that in all these AML patients, the peaks of the fluorescence-intensity profiles obtained with anti-H-366 were noticeably less than those obtained with anti-H-25, indicating that the density of antigen H-25 is higher than antigen H-366 on a substantial number of these blast cells. This observation is similar to what was found for peripheral blood LGLs (Fig 1), where the density of antigen H-25 was

*Nonadherent, light-density normal bone marrow cells were separated by FACS IV into H-25 positive (+), H-25 weakly positive (+/−), and H-25 negative (−) cells. Cell differentials were obtained from May-Grunwald-Giemsa stained cytocentrifuge smears.

†Values represent the mean (± 1 SD) of 500 cells counted for three separate experiments.

‡Values represent the mean (± 1 SD) of the total respective cell types recovered for three experiments. See legend to Table 2 for description of cell types listed.

Fig 5. FACS IV separation of peripheral blood hematopoietic colony-forming cells using MoAbs H-25 and H-366. FACS IV-sorted cell fractions were obtained after reaction of nonadherent, light-density peripheral blood MNC with MoAbs H-25 and H-366 separately. Bars and vertical lines represent the mean % (± 1 SD) of the total number of colonies recovered after sorting for three separate experiments. The number of colonies per 3×10^5 unseparated MNC were 39 ± 18 BFU-E and 11 ± 8 CFU-GM.

also found to be higher than H-366 on peripheral blood LGLs and also for normal bone marrow (Table 2) where a higher number of blasts were found to be H-25⁺.

Both antigens were also expressed by the blast cells from two patients with T-ALL; however, in both cases antigens H-25 and H-366 were equally expressed. In one pre-B, Calla⁺ ALL patient, 60% and 34% of the blasts were positive for H-25 and H-366 respectively. Finally, in another pre-B, Calla⁺ ALL patient, 25% and 14% of the cells were H-25⁺ and H-366⁺ respectively. It must be emphasized, however, that in both of these pre-B, ALL cases, both H-25 and H-366 positive cells were weakly fluorescent.

Expression of H-25 and H-366 antigens on human cell lines. Table 1 gives the results obtained by testing some human cell lines for reactivity with antibodies H-25 and H-366. The parent T-ALL cell line, HSB-2, and the monocytic cell line, U937 were both strongly reactive (>95%) with H-25 and H-366. Furthermore, both antigens were found to

Fig 7. Separation of peripheral blood hematopoietic colony-forming cells using MoAbs and immune rosetting. Nonadherent, light-density peripheral blood MNC were reacted with MoAbs H-25, H-366, Mo-1, and B-1 separately and separated into antigen positive and negative cell fractions by indirect immune rosetting. Bars and vertical lines represent the mean % (± 1 SD) of the total number of colonies recovered after rosetting. The number of experiments are given in parentheses. The average percent recoveries of CFU-GM and BFU-E were similar to the average total cell recovery (78%). The number of colonies per 3×10^5 unseparated MNC were 53 ± 17 BFU-E and 12 ± 2 CFU-GM.

be equally expressed by these two cell lines. Both the myeloblastic cell line, KG-1, and the promyelocytic cell line, HL-60, were H-25⁺; however, the density of antigen H-25 was lower on KG-1 and HL-60 cells than on HSB-2 and U937 cells. In addition, while KG-1 cells contained 25% of weakly staining H-366⁺ cells, the HL-60 cell line did not express this antigen. Of the B cell lines tested, all Calla⁻, Epstein-Barr virus (EBV)-transformed B cell lines (including one that contained the Philadelphia [Ph¹] chromosome^{21,28}) were found to be negative for H-25 and H-366, while the two human B cell lymphoma cell lines, SK-DHL-2 and SK-BU-1-Bt(8;14)-1, both of which are Calla⁺ and

Fig 6. Separation of bone marrow hematopoietic colony-forming cells using MoAbs and immune rosetting. Nonadherent, light-density bone marrow cells, after separately reacting with MoAbs H-25, H-366, Mo-1, and B-1, were separated into antigen positive and negative cell fractions by indirect immune rosetting using bovine RBC coated with goat antimouse IgG. Bars and vertical lines represent the mean % (± 1 SD) of the total number of colonies recovered after rosetting. The number of experiments are given in parentheses. For these experiments the average percent recoveries of colony-forming cells were similar to the average total cell recovery (74%). The number of colonies per 5×10^4 unseparated bone marrow cells were 88 ± 25 CFU-E, 44 ± 14 BFU-E, 210 ± 116 day-7 CFU-GM and 37 ± 18 day-14 CFU-GM.

*Light-density bone marrow or peripheral blood cells from leukemic patients were reacted with antibodies H-25 and H-366 separately, washed, stained with FITC-conjugated F(ab')₂ fragments of goat antimouse IgG, and analyzed by FACS IV. >85% of the light-density cells were blasts (determined by May-Grunwald-Giemsa stain morphology) in all cases.

†AML, acute myelogenous leukemia; APL, acute promyelocytic leukemia; AMOL, acute monocytic leukemia; T-ALL, T cell acute lymphocytic leukemia.

contain the t(8;14) translocation,^{19,20,29} each contained approximately 30% of weakly fluorescent H-25⁺ cells.

DISCUSSION

In the present studies we have confirmed the previous observations of Bai et al⁷ showing that antigens H-25 and H-366 are expressed by human NK cells and have extended these observations to also show that both these antigens are additionally expressed by normal human bone marrow immature cells of the myeloid series. These cells included the majority of blasts and promyelocytes, with sequentially fewer of the more mature cells of the myeloid series. Both antigens were also found on the majority of bone marrow monocytes, which is consistent with previous studies⁷ demonstrating that they are expressed by a substantial number of peripheral blood monocytes.

Of particular interest in the results reported herein was our observation of the distribution of antigens H-25 and H-366 on erythroid and granulocytic/monocytic colony-forming units. H-25 was found to be expressed by all bone marrow CFU-E and the majority of the more primitive BFU-E from both bone marrow and peripheral blood. CFU-GM expression of antigen H-25, on the other hand, was more variable, with significant numbers of both day-7 and day-14 CFU-GM being found both in the positive and negative fractions. The results of the cell-sorting experiments in Fig 4 suggest that this variability may be due to low antigen expression, since substantial numbers of both day-7 and day-14 CFU-GM were sorted into an H-25 weakly positive cell fraction. A significant number of CFU-GM from peripheral blood was also found to be H-25⁺; however, the cell-sorting method detected fewer than that found by immune rosetting. This disparity again may be explained by the fact that in the sorting experiments a window of cells, which were routinely gated out to minimize overlap between antigen positive and antigen negative cells, may include a proportion of H-25 weakly positive CFU-GM that can be detected by the method of immune rosetting.

Similar to H-25, we also found antigen H-366 to be expressed by virtually all bone marrow CFU-E, but, in contrast to H-25, antigen H-366 was found on a lower number (approximately 50%) of BFU-E from both bone marrow and peripheral blood. Also in contrast to antigen H-25, H-366 was not expressed by any significant number of CFU-GM from either bone marrow or peripheral blood.

In testing a variety of human cell lines as well as fresh blast cells from a limited number of leukemic patients in the present studies, our results (Tables 1 and 5) indicate that antigens H-25 and H-366 are expressed both in T-ALL and myeloid leukemias; however, it should be noted that the promyelocytic cell line, HL-60, while being H-25⁺, did not express the H-366 antigen. The absence of the latter antigen on HL-60 cells is an interesting observation, since we did find H-366 to be expressed by a significant number (mean = 36%, Table 2) of promyelocytes from normal bone marrow. It may be that the more differentiated H-366 antigen negative promyelocytes (since H-366 antigen is found on some promyelocytes but not on myelocytes, Table 2) represent the normal counterpart to HL-60 promyelocytic cells.

With regard to their weak expression by only those B cell lines that are Calla⁺ (Table 1) as well as being weakly expressed on a proportion of fresh blast cells from two Calla⁺, Pre-B ALL patients (Table 5), these results, taken together, suggest that antigen H-25 (and possibly H-366) may also be weakly expressed on immature B cells having a Calla⁺ phenotype; however, a more extensive number of B cell lines as well as patients with hematologic malignancies of B cell origin will have to be tested to confirm this.

Recently several other MoAbs that react with many or all NK cells have been described. To date these include Leu-7,¹⁴ N901,¹³ Mo-1,⁸ B73.1,³⁰ Leu-11,³¹ Lyt-3, 3A-1, and OKT10.³² However, the previously reported characterization of antigens H-25 and H-366 with regard to their respective molecular weight and cellular distribution indicates that MoAbs H-25 and H-366 are distinct from these other reported antibodies.⁷ Moreover, the results reported in the present studies further indicate that antigens H-25 and H-366 are of particular interest since they were found to be additionally expressed on a significant number of bone marrow immature myeloid cells, including hematopoietic colony-forming units (particularly CFU-E and BFU-E). Of these other NK cell-reacting MoAbs mentioned above, only OKT10 has been found to react with hematopoietic precursor cells. Thus, Sieff et al,³³ in cell-sorting experiments, have shown the OKT10 antigen to be expressed by the majority of bone marrow BFU-E, a proportion of CFU-E, and CFU-GM, as well as myeloblasts, promyelocytes, and some myelocytes. It was also shown to be expressed by >95% thymocytes and bone marrow TdT⁺ cells.

Thus, while OKT10 (similar to H-25 and H-366) is expressed by LGLs, immature myeloid cells, and thymocytes, it can be distinguished from H-25 and H-366, since the OKT10 antigen has been reported to have a molecular weight of 45 kilodaltons,³⁴ whereas H-25 and H-366 antigens have molecular weights of 96 kilodaltons and 53 kilodaltons respectively.⁷

Since fresh peripheral blood NK cells as well as in vitro-established cloned NK cell lines³⁵ express several cell surface antigens that are also found on thymocytes, T cells (T11, T8), and cells of myeloid lineage (Mo-1, B73.1), their origin and developmental lineage is still controversial. Our observations that antigens H-25 and H-366 are expressed by all three types of cells confirm the uncertainty of NK cell lineage. However, the present finding that antigens H-25 and H-366 are also expressed by bone marrow myeloid precursor cells provides additional evidence^{36,37} that circulating NK cells, like other lymphoid and myeloid cells, are bone marrow derived.

Although the functional roles that antigens H-25 and H-366 have on NK cells are presently unknown, previous studies⁷ have shown that neither antibody blocks NK or K cell activity. With regard to their presence on bone marrow immature myeloid cells, their patterns of expression make it conceivable that they may be involved in proliferation and differentiation events. It is well known, for example, that both monocytes and NK cells exert a regulatory role on the proliferation and differentiation of hematopoietic progenitor cells^(1-3,38-40) and, since both monocytes and NK cells express both antigens, it is possible that antigens H-25 and H-366

may mediate a complex network of cell-cell interactions between monocytes, NK cells, and hematopoietic precursor cells. Experiments to test this hypothesis are currently in progress in our laboratory.

Finally, with appropriate purification strategies, MoAbs H-25 and H-366 may prove to be very useful reagents for isolating immature myeloid bone marrow cells to study hematopoietic cell proliferation and differentiation once

mature NK cells and monocytes have been depleted using other readily available anti-NK and antimonocyte reagents.

ACKNOWLEDGMENT

The authors wish to thank Lana Borzak for her excellent assistance in the preparation of this manuscript and Dr David Golde of UCLA for a generous supply of Mo T cell line-conditioned medium.

A Monoclonal Antibody Detecting a Novel Antigen Expressed in the HTLV-I-Infected Cells

Fumiyo Tsubai, Yuzi Namba, Michiaki Kohno, Shuichi Hanada, Makoto Matsumoto, Mikihiro Shamoto, and Masao Hanaoka

A monoclonal antibody, FTF 148, was prepared by hybridizing murine myeloma cells (NS-1) and spleen cells of BALB/c mice immunized with cultured cells derived from an adult T cell leukemia (ATL) patient (KUT-2 cells). This monoclonal antibody reacted with all of the human T cell leukemia virus I (HTLV-I)-infected cell lines tested but did not react with other T cell lines derived from acute lymphocytic leukemia, Epstein-Barr virus-transformed B cell lines, or an erythroleukemic cell line. This monoclonal antibody was not directed to viral antigens because it reacted equally well with almost all KUT-2 and MT-1 cells, only 1% to 3% of which were ATL-associated antigen-

positive. In contrast to interleukin 2 receptors expressed on both ATL cells and normal phytohemagglutinin-stimulated blasts, this antigen was not expressed on the latter cells. The antigen, mainly expressed on the cell membrane, was analyzed by metabolic labeling with ^3H -leucine and surface labeling with ^{125}I followed by cell lysis and immunoprecipitation with the FTF 148 antibody. The findings obtained by sodium dodecyl sulfate-polyacrylamide gel electrophoresis revealed that p50 and p74 proteins were specifically precipitated and the antigen was also different from the product of the Xs gene of HTLV-I.

© 1987 by Grune & Stratton, Inc.

ADULT T CELL LEUKEMIA (ATL) is a particular type of T cell malignancy first reported by Takatsuki et al.^{1,2} Clinical features of ATL include high white cell counts, frequent skin lesions, hepatosplenomegaly, lymphadenopathy, and a rapidly fatal terminal course. The human type C retrovirus human T cell leukemia virus I (HTLV-I) was first isolated from cultured T cells derived from a patient with a cutaneous T cell lymphoma (mycosis fungoides) and subsequently isolated from cell lines derived from ATL patients.³⁻⁵ Seroepidemiological and molecular biologic analyses suggested that HTLV-I is associated with ATL and plays a causative role in the leukemogenesis of ATL.⁵ However, studies revealed that this virus does not have cell-derived oncogenes and the integration site varies from one patient to another.^{6,7} Therefore, the mechanism of leukemogenesis by HTLV-I still remains to be elucidated. The HTLV-I genome has been shown to carry the Xs gene, and its products (P_x) enhance the transcription of its own long terminal repeat.⁸⁻¹⁰ This protein might also activate cellular gene expression, and this activation might be associated with T cell transformation.

To identify the cellular gene product necessary to maintain the proliferation of ATL cells, we tried to obtain monoclonal antibodies that react specifically with ATL-

derived cells irrespective of the production of HTLV-I virus. We obtained a monoclonal antibody, FTF 148, for this purpose. The antigen detected with this monoclonal antibody proved to be different from the interleukin 2 (IL 2) receptor, the Ia-like antigen, viral antigens and the Xs gene product. We report the specificity of the monoclonal antibody together with some characterization of the new antigen.

MATERIALS AND METHODS

Cells. The HTLV-I-infected cell lines KUT-1 and KUT-2 were established from the peripheral blood lymphocytes (PBL) of ATL patients by cultivation in RPMI 1640 medium supplemented with 10% human cord serum.¹¹ UW-4 is the IL 2-dependent cell line derived from PBL of an ATL patient. Three T cell lines (MT-1, MT-2, and HUT-102) and three B cell lines derived from ATL patients (KUT-3, ATL-B-1, and ATL-B-2) were also used as HTLV-I-infected cell lines. Five cell lines (MT-1, MT-2, KUT-1, KUT-2, and HUT-102) were cloned lines. The integration of the proviral DNA was confirmed in many cell lines (MT-1, MT-2, KUT-1, KUT-2, KUT-3, and HUT-102). As negative-control target cells we used three T cell lines derived from acute lymphocytic leukemia (CCRF-CEM, HSB-2, and MOLT-4), two Epstein-Barr virus (EBV)-transformed B cell lines, another B cell line (Raji), and the K-562 cell line. In some experiments, PBL from healthy adults were separated with Ficoll-Paque and the cells were cultured with phytohemagglutinin-P (PHA-P) or with concanavalin A (Con A) (2 $\mu\text{g}/\text{mL}$) for 48 hours and were used as negative-control target cells. These cells were cultured in RPMI 1640 medium supplemented with 10% fetal calf serum (FCS) and antibiotics. This medium is referred to as RPMI complete medium.

Preparation of monoclonal antibodies. BALB/c mice were immunized twice at 1-week intervals by intraperitoneal (IP) injections of 1.0×10^7 KUT-2 cells followed by a booster immunization with the same dose of KUT-2 cells using the same route. Four days after the last immunization, the mice were sacrificed, and their spleen cells (1×10^8 cells) were fused with mouse myeloma cells (NS-1, 2×10^7 cells) using 45% polyethylene glycol 4000 (Merck, Darmstadt, West Germany). The cells were seeded in 96-well flat-bottomed tissue culture plates (No. 25860, Corning Glass Works, Corning, NY) at a concentration of 1.0×10^5 spleen cells per well with normal spleen cells from BALB/c mice (3×10^5 cells/well) as feeder cells. The cells were cultured in RPMI complete medium supplemented with hypoxanthine (100 $\mu\text{mol}/\text{L}$), thymidine (16 $\mu\text{mol}/\text{L}$) and aminopterin (0.1 $\mu\text{mol}/\text{L}$), and approximately 1,200 hybridoma clones were established. The clones that reacted specifically with the ATL-derived cell line were selected by the

following screening program. In the first screening step, the culture supernatants (CS) of hybridoma clones that reacted with the majority of acetone-fixed KUT-2 cells were selected by an indirect immunofluorescence method. In the next step, the CS reactive with either EBV-transformed B cells or PHA-stimulated PBL were eliminated. In the third step, the CS reactive with PBL from an ATL patient cultured for four hours were selected. In the last screening step, the CS reactive with non-ATL T cell lines (HSB-2, CEM, and MOLT-4) were eliminated. Two hybridoma clones were selected by this screening program (FTF 148 and FTG 193). Although these clones were prepared independently, the staining patterns of the ATL-derived cell lines under indirect immunofluorescence were almost identical. The findings obtained using FTF 148 are reported here.

Immunoelectron microscopic studies. The cultured cells were harvested and washed three times with Dulbecco's phosphate-buffered saline (PBS) containing bovine serum albumin (BSA) (100 $\mu\text{g}/\text{mL}$). The cells were pelleted by centrifugation and fixed in periodate-lysine-paraformaldehyde (PLP) according to the method of Mclean and Nakane.¹² After a two-hour fixation at 4 °C, the pellets were washed with PBS containing 10% sucrose and further washed with an increasing series of sucrose in PBS. Finally they were placed in PBS containing 20% sucrose and 10% glycerol. The fixed cells were embedded in an OTC compound (Miles Laboratories, Naperville, IN) and frozen in liquid nitrogen. Ten-micrometer-thick frozen sections were placed on slides, overlaid with diluted monoclonal antibody (2,000-fold diluted ascites), and incubated in a humidified chamber at room temperature for two hours. Then the sections were reacted with biotinylated horse antimouse IgG for two hours followed by incubation with both an avidin-biotinylated peroxidase complex and a peroxidase-mouse antiperoxidase complex for two hours at room temperature. The sections were then fixed in 2% glutaraldehyde for ten minutes at room temperature, washed with PBS, and incubated with 3,3'-diaminobenzidine tetrahydrochloride (DAB) and hydrogen peroxide. After postfixation in OsO_4 for one to two hours, they were dehydrated in a graded series of alcohol every five to ten minutes and embedded in inverted gelatin capsules filled with epoxy resin. The sections were cut on an LKB Ultratome (Stockholm) with a diamond knife. The ultrathin sections were stained with uranyl acetate and lead citrate. Both stained and unstained sections were examined with a JEM 100 CX electron microscope (Jeol, Inc, Peabody, MA).

Radioactive labeling and immunoprecipitation. KUT-2 cells were labeled by two independent methods: cell surface antigen was labeled with ^{125}I by the lactoperoxidase method,¹³ and proteins were metabolically labeled with ^3H -leucine for 16 hours (10 $\mu\text{Ci}/\text{mL}$ in leucine-free RPMI 1640 medium supplemented with 10% FCS). The labeled cells (1×10^7 cells) were washed three times with PBS and then treated for ten minutes at 4 °C with 2 mL of lysis buffer (50 mmol/L Tris-HCl, pH 8.0; 100 mmol/L NaCl; 0.5% sodium deoxycholate). The lysates were sonicated and were cleared by centrifugation at 7,000 g for 30 minutes at 4 °C. The samples (200 μL) were incubated with 6 μg IgG of FTF 148 or with normal mouse IgG (50 μL) for four hours at 4 °C and for another two hours with 120 μg IgG of rabbit antimouse Ig (120 μL). They were further incubated with 200 μL of a 40% suspension of protein A-Sepharose 4B for 30 minutes at 4 °C, and the gel was washed twice with the lysis buffer, twice with PBS containing 0.1% BSA and further washed twice with BSA-free PBS. The immunoprecipitates were suspended in 200 μL of the electrophoresis sample buffer (0.0625 mol/L Tris-HCl, pH 6.8; 2.3% sodium dodecyl sulfate [SDS]; 5% 2-mercaptoethanol) and heated at 50 °C for two hours. After centrifugation, the supernatants (30 μL) were introduced into the slots of analytic SDS-polyacrylamide gel and separated at a constant voltage (100 V). After electrophoresis, the gels were stained

and processed for autoradiography (^{125}I surface label) and fluorography (^3H -leucine metabolic label).

Immunofluorescence assay. For the assay of the reactivity of the FTF 148 antibody, an indirect immunofluorescence method was used. The smeared target cells were fixed with cold acetone (-20 °C) for five minutes and incubated in a moisture chamber for 30 minutes at room temperature with CS or Ig partially purified from the ascites of mice that had been injected with the hybridoma cells. The slides were washed three times with PBS containing BSA (100 $\mu\text{g}/\text{mL}$) and incubated for 30 minutes with fluorescein isothiocyanate (FITC)-conjugated Ig of rabbit antimouse Ig absorbed with human Ig conjugated to Sepharose 4B and human spleen acetone powder. After two washings with PBS containing BSA, the slides were again washed twice with BSA-free PBS and mounted in 95% glycerin. In some experiments viable cells were stained by the same procedure, washed as before, suspended in Dulbecco's PBS and observed under a fluorescence microscope.

Partial purification of IgG from ascites. The cloned hybridoma cells were implanted IP in pristane-primed BALB/c mice, and the ascites fluids were collected. The IgG fraction was prepared from ascites by repeated precipitation with 45% saturated ammonium sulfate (pH 6.2). The resulting precipitates were dialyzed against PBS.

Immunoglobulin subclass determination. The CS of the hybridoma cells were concentrated tenfold with Minicon B15 (Amicon Corp, Danvers, MA), and the immunoglobulin subclass was determined by the double-immunodiffusion method using isotype-specific rabbit antimouse immunoglobulin.

Tunicamycin treatment of KUT-2 cells. KUT-2 cells (1×10^6) were incubated for 16 hours in RPMI complete medium in the presence of tunicamycin (0.8 $\mu\text{g}/\text{mL}$) and were used for the viable cell immunofluorescence study. For metabolic labeling of the tunicamycin-treated cells, the cells were incubated on leucine-free RPMI 1640 medium supplemented with 10% FCS and tunicamycin (0.8 $\mu\text{g}/\text{mL}$) for one hour, then ^3H -leucine (10 $\mu\text{Ci}/\text{mL}$) was added to the medium, and the incubation was continued for 15 hours.

Chemicals and reagents. The monoclonal antibodies against the human IL 2 receptor (HIE1, H-31, and H-A26)¹⁴ were kindly provided by Dr Y. Hinuma and Dr K. Sugamura. Tunicamycin, an inhibitor of N-linked glycosylation,¹⁵ was kindly provided by Dr G. Tamura. The FITC-conjugated IgG of rabbit against mouse IgG was prepared in our laboratory. The other antibodies were isotype-specific rabbit antimouse immunoglobulin obtained from Zymed Laboratories (San Francisco) and peroxidase mouse antiperoxidase (mouse PAP) from E-Y Laboratories, San Mateo, CA. Avidin-biotinylated peroxidase was purchased from E-Y Laboratories and protein A-Sepharose 4B from Pharmacia P-L Biochemicals, Uppsala, Sweden. ^3H -leucine and ^{125}I were purchased from New England Nuclear, Boston. RPMI 1640 was obtained from GIBCO, Grand Island, NY; FCS from M.A. Bioproducts, Walkersville, MD; Con A and PHA-P from Pharmacia P-L Biochemicals; DAB from Dojin Chemical Institute, Japan, and Ficoll-Paque from Pharmacia P-L Biochemicals. Sodium deoxycholate was purchased from Nakarai Chemicals, Japan.

RESULTS

Preparation and reactivity of the FTF 148 monoclonal antibody. From approximately 1,200 hybridoma clones, two clones (FTF 148 and FTG 193) were selected by the screening program presented in Materials and Methods. Although the immunoglobulin isotypes of FTF 148 and FTG 193 were IgG₁ and IgA respectively, the staining pattern of the immunofluorescence was almost the same, and the antigen reactive with FTF 148 antibody was characterized.

First, the reactivity of this antibody with various kinds of human lymphoid cell lines was examined by the indirect immunofluorescence method using viable cell or acetone-fixed smeared cells (Table 1). The FTF 148 antibody reacted with all of the HTLV-I-infected cell lines tested. This antibody, however, did not react with other T cell lines derived from acute lymphocytic leukemia (HSB-2, CEM, and MOLT-4), EBV-transformed B cell lines, or an erythroleukemic cell line (K562). The only exception was the Raji cell line in which approximately 1% of the cell population was positively stained by a membrane immunofluorescence method. The possibility that this antigen, mainly expressed on cell membranes, is identical with the IL 2 receptor molecule expressed in abundance in HTLV-I-infected cells was ruled out because normal PBL stimulated with PHA or Con A reacted with a monoclonal antibody against the IL 2 receptor (HIEI, H-31, and H-A26) but did not react with the FTF 148 monoclonal antibody (Table 2). The expression of the antigen detected with the FTF 148 monoclonal antibody correlated well with the integration of HTLV-I proviral DNA in the cells but did not correlate with the expression of the ATL-associated antigen (ATLA) detected with anti-ATLA-positive human serum (Table 3). As presented in Table 3, the FTF 148 antibody reacted with more than 90% of the KUT-2 and MT-1 cells, only 1% to 3% of the cells of which expressed the ATLA. This antibody also reacted with more than 90% of the KUT-1 cells in which ATLA-positive

Table 2. Reactivity of Lectin-Stimulated PBL With FTF 148 Antibody and Monoclonal Antibodies Against the IL 2 Receptor

Antibody	Percentage of Fluorescence-Stained Cells in		
	Nonstimulated PBL*	PHA-Stimulated PBL†	Con A-Stimulated PBL‡
FTF 148	0	0	0
HIEI	<2	40-60	25-40
H-31	<2	45-60	20-35
H-A26	<1	40-60	20-40

The percentage of positive cells was determined by an indirect immunofluorescence method using viable cells. Three to five healthy adult PBL were used for each antibody.

*PBL cultured for 48 hours without lectin stimulation. Fresh PBL were also stained with FTF 148 antibodies (four cases).

†PBL stimulated with PHA-P (2 µg/mL) for 48 hours.

‡PBL stimulated with Con A (2 µg/mL) for 48 hours.

cells were not detected. Furthermore, this antibody reacted with almost all of the PBL that had been taken from an ATL patient and cryostocked after a four-hour culture although ATLA-positive cells were still very rare. Because anti-ATLA-positive antiserum mainly detects *env* and *gag* protein, the FTF 148 antibody may not be directed to the viral antigen of HTLV-I.

The reactivity of this antibody to fresh PBL obtained from ATL patients was examined by a viable cell surface immunofluorescence method. In some cases a significant percentage of PBL reacted with this antibody (Table 4). In most cases, the ATL cells in the peripheral blood did not express this antigen *in vivo* thereby making it necessary to elucidate the mechanism of expression of this antigen in relation to the expression of the HTLV-I genome.

Localization of the antigen in ATL-related cultured cells. The acetone-fixed KUT-2 cells demonstrated a strongly positive immunofluorescence reaction mainly on the cell membrane and a relatively weak reaction in the cytoplasm. The antigenic determinant of this antigen is exposed to the external lipid bilayer of the plasma membrane because viable cells reacted with this antibody very strongly. Immunoelectron microscopic analysis of PLP-fixed cells using an immunoperoxidase technique revealed that in MT-2 cells this monoclonal antibody reacted with some components of the plasma membrane (Fig 1). The linear pattern of a positive peroxidase reaction was usually observed, and the

PBL were separated from peripheral blood with Ficoll-Paque, and the percentage of positive cells was determined by an indirect immunofluorescence method.

*More than 40% of PBL were positively stained in two out of four cases.

†Anti-ATLA-positive adults. Another seropositive adult in this group did not have any positively stained cells in PBL.

localization of the reaction was not correlated to that of virus particles that were abundant in the vesicular structure in the cytoplasm and also in the extracellular space. In HUT-102 cells, not only was the plasma membrane positively stained by an immunoperoxidase method, but also the rough endoplasmic reticulum and some parts of the nuclear membrane were positively stained (Fig 2). These results coincide well with the findings obtained using the acetone-fixed smeared cells.

Characterization of the antigen detected with the FTF 148 antibody. For biochemical analysis, KUT-2 cells were labeled with ^3H -leucine for 16 hours, processed as described in Materials and Methods and subjected to SDS-polyacrylamide gel electrophoresis (PAGE) on 10% slab gels. The fluorographic patterns of the material immunoprecipitated with the FTF 148 antibody and the material immunoprecipitated with normal mouse IgG revealed that two proteins were specifically precipitated (Fig 3). The monoclonal antibodies against other cellular components (eg, antihuman *c-myc*, anti-Px) did not precipitate this antigen. These proteins had apparent molecular weights (mol wt) of 74,000 and 50,000. Treatment of KUT-2 cells with tunicamycin (0.8 $\mu\text{g}/\text{mL}$) so

as to decrease the ^3H -glucosamine incorporation into the cellular proteins by 95% did not reduce the apparent mol wt of these proteins, which suggests that these proteins did not have a long N-linked carbohydrate chain. The tunicamycin-treated cells had as many antigenic determinants as non-treated cells on the cell membrane as evidenced by a surface immunofluorescence study.

From the ^{125}I surface-labeled material, these two proteins were also specifically precipitated, thus suggesting that at least a part of these proteins was exposed to the exterior of the plasma membrane (Fig 4). The relationship between these two proteins is still unclear. These two proteins may form a complex on the plasma membrane, and the antibody may be directed to one of them.

This antigen is not the product of the Xs gene of HTLV-I (Px) because the latter protein has been reported to be distributed in the nucleus and cytoplasm.^{16,17} We have recently obtained a monoclonal antibody against the product of a fourth open reading frame of the Xs gene (Px IV) and confirmed this result (unpublished observations). The analysis of the detailed structure and the function of this antigen, supposedly a product of a cellular gene activated by a transacting viral gene product, is now in progress.

DISCUSSION

ATL is considered to be caused by an HTLV-I infection based on proviral DNA analysis and seroepidemiological studies, but the relationship between viral infection and leukemogenesis is still unclear. Recently Sodroski et al showed that there exists a transacting factor in HTLV-I-infected cells and this factor may be the product of the Xs region of the HTLV-I genome.¹⁰ This factor is now believed to promote cellular gene activation, and the product of the latter is responsible for cell transformation. In this respect, it is important to analyze the cellular gene products newly expressed by the infection of HTLV-I. The HTLV-I-infected leukemic cells generally have a surface phenotype characteristic of mature helper T cell and express the IL 2 receptor in abundance and HLA-DR antigens.¹⁸⁻²⁰

Fig 1. Immunoelectron micrograph of MT-2 cells. The plasma membrane is positively stained with the FTF 148 antibody. Virus particles in the vesicular structure are not stained (arrow). (A) Micrograph of MT-2 cells stained with uranyl acetate and lead citrate (original magnification $\times 7,300$). (B) Enlarged micrograph of MT-2 cells in which virus particles in a vacuole are visualized (original magnification $\times 31,200$).

Fig 2. Immunoelectron micrograph of HUT-102 cells. In HUT-102 cells not only is the plasma membrane positive with the FTF 148 antibody, but the rough endoplasmic reticulum and some parts of the nuclear membrane are positively stained (arrow in B). (A) was stained with uranyl acetate and lead citrate (original magnification $\times 7,300$), but (B) was not stained (original magnification $\times 14,600$).

We prepared a new monoclonal antibody, FTF 148, and detected a novel antigen specifically expressed in HTLV-I-infected cells. This antigen is expressed in both T and B cell lines. According to our experience, the establishment of B cell lines from PBL of ATL patients is easier than that from PBL of normal persons. As demonstrated by Sugamura et al, HTLV-I infects B cell lines and induces the expression of IL 2 receptor molecules.²¹ This antigen is, however, different from the IL 2 receptor because the latter is also expressed in lectin-stimulated normal PBL but the former is not. Because the IL 2 receptor molecules of HTLV-I-infected T cells are, for the most part, low-affinity IL 2 receptor molecules, it was necessary to rule out the possibility

that the FTF 148 antibody reacted specifically with them. We used three monoclonal antibodies prepared and characterized by Tanaka et al¹⁴ to examine whether low-affinity IL 2 receptor molecules were well expressed in our lectin-stimulated PBL. The antibody specific to low-affinity IL 2 receptor molecules (H-A26) reacted with our lectin-stimulated PBL to the same extent as the antibody specific to high-affinity IL 2 receptor molecules (HIE1), and the antibody reacted with both high- and low-affinity molecules (H-31) by a membrane immunofluorescence method. The mol wt of this antigen and the IL 2 receptor is different. The anti-IL 2 monoclonal antibodies precipitated glycoproteins with mol wts of 60,000 to 65,000,²²⁻²⁴ whereas the FTF 148 antibody precipitated proteins with mol wts of 74,000 and 50,000. Taken together, the antigen presented in this paper is different from the IL 2 receptor. The possibility that the FTF

Fig 3. Immunoprecipitation and SDS-PAGE of ^3H -leucine-labeled KUT-2 cells. The cells were metabolically labeled with ^3H -leucine for 16 hours and subjected to immunoprecipitation with the FTF 148 antibody (A-1) or with normal mouse IgG (A-2). (B) KUT-2 cells were incubated with tunicamycin ($0.8 \mu\text{g}/\text{mL}$) for one hour, then ^3H -leucine was added, and the incubation was continued for 15 hours. The cells were subjected to immunoprecipitation with the FTF 148 antibody (B-1) or normal mouse IgG (B-2).

Fig 4. Immunoprecipitation and SDS-PAGE of ^{125}I -labeled KUT-2 cells. The cells were surface labeled with ^{125}I and subjected to immunoprecipitation with the FTF 148 antibody (1) or normal mouse IgG (2).

148 antibody is directed to an Ia-like antigen was ruled out because this antibody did not react with PBL from normal adults or with the B cell leukemia cell lines (B-ALL and B-CLL).

The antigen detected with the FTF 148 antibody is considered to be different from viral antigen because (1) this antibody reacted with the vast majority of MT-1 and KUT-2 cells, though the percentage of ATLA-positive cells in these cell lines was lower than 3%; (2) this antibody reacted with the ATL cells cultured for four hours although ATLA-positive cells were still very rare; (3) in MT-2 cells, many virus particles were found in the vesicular structure as well as in the extracellular space by electron microscopy, and these particles reacted with anti-ATLA-positive human serum and the rabbit antibodies raised against the highly purified virus solubilized with Triton X-100,²⁵ whereas, the FTF 148 antibody reacted only with the plasma membrane of MT-2 cells; and (4) HTLV-I-specific polypeptides exist in the cells in diverse forms.^{26,27} The *gag* gene products are synthesized as 53,000-dalton polypeptides and are proteolytically cleaved to three low-mol wt *gag* proteins (P19, P24, and P15). The *env* protein is synthesized as 46,000-dalton polypeptides and are glycosylated to 62,000-dalton molecules. These proteins are cleaved to 46,000- and 20,000-dalton molecules. After tunicamycin treatment of HTLV-I-infected cells, the 46,000-dalton polypeptides are not glycosylated, and 62,000-dalton molecules are not formed. These results strongly suggest that the antigen reactive with the FTF 148 antibody is different from viral proteins and their precursors.

The other genes that produce proteins are the *pol* and *Xs* genes. The *pol* gene protein of the retrovirus that is known as reverse transcriptase is in general synthesized as a *gag-pol* read-through product and is often detected as a 180,000- to 200,000-dalton polypeptide.^{28,29} The nucleotide sequence of HTLV-I suggested that the *pol* gene of this virus could code for a 99,000-dalton protein.⁶ Neither *gag-pol* product nor *pol* gene product has been identified yet in HTLV-I-infected cells, though the reverse transcriptase activity was clearly demonstrated on HTLV-I virion particles.^{5,30} One of the unique features of HTLV-I is its gene termed *Xs*, which resides downstream of the *env* gene and is flanked by 3'LTR. Recently, using rabbit antibodies to the synthetic oligopeptide specific to the predicted amino acid sequences of the product of the *Xs* region, 40,000-dalton proteins were detected in HTLV-I-infected cells.^{31,32} Previously Sugamura et al reported that a 40,000-dalton protein was detected with the serum of ATL patients in almost all the cell lines infected with HTLV-I but not in the uninfected cell lines.²⁰ We prepared a monoclonal antibody (MI 73) against the synthetic oligopeptide of the COOH terminal region of pX IV (the product of a fourth open reading frame of the *Xs* gene) that specifically reacted with this 40,000-dalton protein. By an immunofluorescence method, the 40,000-dalton protein was found to be distributed in the cytoplasm (polysome) and

nucleus of the major population of HUT-102, KUT-1, and KUT-2 cells in which the expression of ATLA was in a minor population (HUT-102, KUT-2) or not expressed at all (KUT-1) (unpublished observation). The pX I-III proteins have not been found yet, but this region may have no essential role for cellular transformation and may not function to synthesize proteins, as suggested by the low homology with HTLV-II. These results strongly suggest that the antigen we detected is different from the *pol* and *Xs* gene products.

We examined the reactivity of the FTF 148 antibody with fresh PBL from ATL patients. In some cases, many PBL reacted with antibody. In the majority of cases, however, only a low percentage of PBL reacted, or no PBL reacted. Franchini et al³³ have recently reported that in a few cases the messenger RNA transcribed from some part of the HTLV-I genome was expressed in fresh PBL obtained from ATL patients. We examined the lymph nodes of ATL patients by an immunohistochemical method with the result that in three patients out of four more than 10% of the lymph node cells expressed this antigen, thus indicating that in the tissue in which ATL cells are very actively proliferating (checked with Ki-67 monoclonal antibody) this antigen is expressed in a high percentage of ATL cells (unpublished observation). These results suggest that gene expression of HTLV-I induces the expression of this antigen. This antigen was expressed 1% to 2% of Raji cells that are not infected with HTLV-I. We presume that in Raji cells that have been cultured for many years, many cellular genes are newly expressed by mutations or chromosome translocations. This antigen has also expressed in the UW-4 cell line derived from an ATL patient and still depends on the presence of IL 2 for its proliferation. There is still a controversy as to whether ATL cells depend on IL 2 or not. The PBL from the ATL patient proliferate very well in the presence of IL 2, and from almost all cases IL 2-dependent permanent cell lines are established. This phenomenon is in high contrast to cultures of PBL from normal persons because the proliferation of the latter cells gradually decreases and it is very hard to establish a permanent cell line. This phenomenon suggests that ATL cells are immortalized by the integration of HTLV-I proviral DNA. From the IL 2-dependent cells derived from ATL lymphocytes, the conversion to IL 2-independent cells rarely occurs. At present we consider that there exist two different stages of ATL with respect to the dependence on IL 2. These results suggest that this antigen may be related to cell immortalization and is a product of certain cellular genes activated by some transacting factor (eg, Px) produced by HTLV-I infection.

ACKNOWLEDGMENT

The authors wish to thank Drs. Y. Hinuma and K. Sugamura for supplying monoclonal antibodies against the IL 2 receptor and Dr M. Hatanaka for helpful discussion.

Spectrum of Natural Antibodies Against Five HTLV-III Antigens in Infected Individuals: Correlation of Antibody Prevalence With Clinical Status

By Genoveffa Franchini, Marjorie Robert-Guroff, Anna Aldovini, Nancy C. Kan, and Flossie Wong-Staal

The genome of the HTLV-III/LAV retrovirus, the etiologic agent of the acquired immunodeficiency syndrome (AIDS), encodes the viral structural proteins (envelope and core proteins), the reverse transcriptase, a transactivation protein (tat-III), as well as two other proteins (3'orf, sor) of unknown function. We studied the prevalence of natural antibodies against envelope, gag, 3'orf, sor, and tat-III in the sera of HTLV-III infected individuals in an attempt to correlate clinical status with seropositivity to specific HTLV-III antigens. We selected 101 sera; 16 were obtained from normal donors with no known risk factors, and 85 were from patients with full-fledged AIDS (28 cases), AIDS-related complex (ARC, 22 cases), and healthy people at risk (homosexuals, intravenous [IV] drug users, relatives of AIDS patients; 35 cases). Seropositivity for antibodies against the envelope (gp41) and gag antigens (p15, p24) was determined by Western blot using disrupted HTLV-III virions. Of the 101 sera, all 16 from nonrisk donors and 3/35 from healthy at-risk donors were negative for antibodies against either the gp41 or p15 and p24. The remaining 82 sera were seropositive for either the gp41

and/or the p15 and p24. All sera were then tested against the three known HTLV-III antigens (3'orf, sor, and tat-III) that have been synthesized in bacteria. Our data indicate that all the HTLV-III antigens tested are immunogenic in vivo. No significant difference in antibody prevalence to gp41 (close to 100%) and to the 3'orf, sor, and tat-III proteins (approximately 50%) was observed with regard to stage of the disease. In contrast, the prevalence of antibodies against the core antigens decreased from approximately 100% in infected people with no clinical signs of disease to 50% in ARC and AIDS patients. The percentage of patients seropositive for all five antigens tested was increased in the AIDS group. These results indicate that the greatest antibody prevalence was obtained using viral envelope antigen and further suggest that screening with the newly identified 3'orf, sor, and tat-III proteins as antigens would confer no further diagnostic advantage. The pattern of natural antibodies observed during disease progression did not suggest any pathogenetic mechanism. © 1987 by Grune & Stratton, Inc.

ACQUIRED immunodeficiency syndrome (AIDS) was first described in the United States in 1981,¹ and since then the disease has reached epidemic proportions.² The syndrome consists of a series of clinical manifestations directly related to the severe immune dysfunction in the affected people, such as opportunistic infections and various disorders such as autoimmune diseases, malignancies, and neurologic manifestations, the pathogenetic origin of which is less obvious. Infection by HTLV-III/LAV is the common denominator among these patients.³⁻⁵ HTLV-III infection correlates with depletion of the OKT⁴⁺ T cells in vivo and in vitro.^{6,7} While the immunodepression observed in patients with AIDS could be a direct consequence of the cytopathic effect of HTLV-III exerted on T cells as it is observed in vitro,⁷ the role played by HTLV-III in the pathogenesis of the various clinical manifestations of the syndrome is still not clear. The molecular cloning and the nucleotide sequencing of HTLV-III^{8,9} allowed the identification of the envelope, polymerase and the core protein genes, and three additional open-reading frames, 3'orf, sor, and tat-III, that encode proteins of 27, 23,¹⁰⁻¹² and 14Kd respectively.¹³ The tat-III protein seems to enhance virus expression in the infected^{14,15} cells and may play a key role in the mechanism of viral replication. The functions of the 3'orf and sor proteins relative to the viral life cycle or the cellular metabolism of infected cells remain to be uncovered. We studied the expression in vivo of these viral genes by analyzing the natural antibody response in infected individuals in an attempt to correlate the stage of the disease and the different clinical manifestations with the expression of specific viral proteins.

MATERIALS AND METHODS

Virus preparation. HTLV-III produced by H9 cells was harvested from 50 liters of cell-free tissue culture media using zonal ultracentrifugation on two sequential ribonuclease-free sucrose gra-

dients as previously described.¹⁶ Purified virus was disrupted in 50 mmol/L Tris-HCl buffer, pH 7.9, containing 0.25% Triton X-100, 20 mmol/L dithiothreitol, 1 mmol/L EDTA, 0.5 mol/L KCl, and 1 mmol/L phenylmethyl sulfonyl fluoride by stirring for one hour at 4 °C. The solubilized virus preparation was dialyzed extensively against phosphate-buffered saline (PBS) and centrifuged for one hour at 100,000 × g. The supernatant fraction was used in Western blot¹⁷ assays following protein estimation by the method of Lowry.¹⁸

Purification of the bacterially synthesized viral proteins. The bacterially synthesized HTLV-III proteins were purified by different methods. The 3'orf protein was obtained from the total cell lysate of E 10 bacteria after solubilization in 50 mmol/L Tris-HCl, pH 8, containing 1.5 mol/L sodium chloride and 8 mol/L urea and application of the extract to a Sephacryl S-300 column. The fractions containing the 3'orf protein were pooled and applied to a Sepharose 4B column coupled with an antibody directed against the amino terminus of the hybrid protein.¹⁰ The 3'orf protein was recovered by elution with 2% formic acid and used in a Western blot assay.¹⁷ The bacterially synthesized 27 Kd 3'orf protein is a hybrid protein that comprises 84% of the 3'orf gene and 36 amino acids derived from the prokaryotic vector.¹⁰ By coincidence the molecular weight of the bacterial protein is the same as the molecular weight of the native protein (p27) detected in infected cells.^{10,11} The sor protein was purified by application of the bacterial lysate¹² to a cation-

exchange Water Protein-Pak Sp-5PW HPLC column and elution with a 25-mL gradient of 0% to 80% 0.75 mol/L NaCl in the equilibration buffer. The bacterial *sor* (p18) is a hybrid protein representing 83% of the *sor* gene. The native protein product has been identified as a 23Kd protein.¹² The tat-III protein was purified¹³ by applying the bacterial lysate to a 15% SDS-polyacrylamide gel. After electrophoresis the 14 Kd protein was eluted from the appropriate gel slice. The 14 Kd tat-III protein expressed in *Escherichia coli* is not a fusion protein but represents the complete protein product of the tat-III gene. It therefore has the same size as the native protein product detected in infected cells.¹³

Western blot analysis of the viral proteins. Lysate of HTLV-III or purified recombinant proteins (3'orf, tat-III, and *sor*) were fractionated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). The proteins were electrophoretically transferred to nitrocellulose sheets as described,¹⁷ and the sheets were incubated for one hour at room temperature with a solution containing 5% nonfat dry milk and 0.01% Antifoam (Sigma, St Louis) in PBS to block nonspecific protein-binding sites. Strips were obtained from the nitrocellulose sheets and individually reacted with human sera diluted 1:100 for one hour at 4°C in the same solution containing 5% nonfat dry milk. After incubation the strips were washed in PBS containing 0.5% sodium deoxycholate and reacted for 20 minutes with ¹²⁵I staphylococcal protein A (5 × 10⁵ cpm/mL). The strips were washed again, and autoradiograms were obtained.

RESULTS

Location of the coding regions for the HTLV-III proteins. A summary of the genes identified in the different open-reading frames of the HTLV-III genome by computer analysis is depicted in the upper part of Fig 1. To date the core proteins p24, p15, have been identified as well as the gp120 and gp41^{3,19,20} for the exterior and transmembrane portion of the envelope respectively. Three other HTLV-III genes have been uncovered by studying the viral c-DNAs,¹⁴ and the features of their spliced mRNAs are summarized in the lower part of Fig 1. The native products of the three genes, 3'orf, *sor*, and tat-III have been identified in infected cells cultured in vitro. The three genes encode proteins p27,¹⁰⁻¹¹ p23,¹² and p14¹³ respectively.

Fig 1. Diagrammatic representation of the HTLV-III genome and of the spliced mRNAs for three protein products. The upper part of Fig 1 displays the HTLV-III genome and the position of the open-reading frames for the six genes that have been identified. The schemes underneath the HTLV-III map include the sequences that are maintained in the mature mRNAs for the 3'orf, *sor*, and tat-III proteins. The white and black dots represent the donor and acceptor sites that are joined together in the mature mRNA. The 5' donor splice site for the *sor* mRNA has not been identified yet. The numbers refer to the position of the sites in the HTLV-III nucleotide sequence.⁹

Correlation of antibody response and stage of the disease. We attempted to correlate the stage of the disease with the prevalence of antibodies against specific viral antigens. We employed 82 human sera seropositive for antibodies against the HTLV-III core proteins (p15 and/or p24) or the gp41 or both. The sera, all obtained from Americans, included 32 samples from healthy individuals at risk for HTLV-III infection; 28 samples from patients with full-fledged AIDS, and 22 samples from American patients with ARC. The patients in the risk group defined 'healthy' included individuals with and without lymphadenopathy (LAS). Among them, three were IV drug users and one was a relative of a patient with AIDS. The rest were homosexuals. ARC patients were staged according to the criteria of the Centers for Disease Control,²⁰ and the group included patients with at least two laboratory findings of immunodysfunction and two clinical manifestations of disease. All the AIDS patients had serious manifestations of disease, including either Kaposi's sarcoma (50%) or opportunistic infections (50%). We also studied 16 human sera seronegative for antibodies against the *gag* and envelope proteins of HTLV-III obtained from a population not at risk for HTLV-III infection and three sera from previously identified virus-positive, antibody-negative healthy carriers.^{21,22} An example of a Western blot of some of these sera using disrupted HTLV-III is given in Fig 2, first panel. The sera were also reacted against the purified 3'orf, *sor*, and tat-III protein products expressed in *E coli* (Fig 2, panels 2, 3, and 4). Some sera from each group of patients (healthy at risk, ARC, AIDS) recognized the bacterially synthesized HTLV-III proteins. Sera of the normal donors (HN) lacking antibodies to the envelope and the core proteins of HTLV-III also did not react with the tat-III and the 3'orf proteins; in contrast some of the normal sera recognized the *sor* protein. The three sera obtained from the healthy virus-positive individuals failed to recognize the 3'orf, *sor*, and tat-III proteins. Later samples from these same individuals seroconverted and became positive for envelope and core antigens.

A histogram of the distribution of natural antibodies against the five HTLV-III proteins analyzed in this study is shown in Fig 3. The antibody prevalence against the envelope antigen gp41 was constant in all phases of the disease. Almost all patients tested were seropositive for this antigen, in agreement with other studies²³ that have shown the viral envelope to be the major target antigen in HTLV-III-exposed individuals. While minor fluctuations in antibody prevalence were observed with disease progression, overall a constant pattern occurred with the 3'orf, *sor*, and tat-III proteins. In the case of these antigens, however, the percentage of seropositive individuals was in the intermediate range of 30% to 65% depending on the antigen. The antibody prevalence to the *gag* antigenic determinants was greatest among the healthy at risk group, as reported also by other investigators.²⁵ When individuals in the early phases of disease were analyzed with regard to the presence or absence of lymphadenopathy, no differences in the antibody prevalence to any of the five antigens were detected.

Specificity of seroreactivity to the bacterially synthesized *sor* protein. As indicated in the histogram of Fig 3, 25% of

Fig 2. The first panel represents the autoradiograph of nitrocellulose strips containing HTLV-III viral proteins from the disrupted virion reacted with various human sera. Panels 2, 3, and 4 represent examples of the reactivity of human sera toward the 3' orf, sor, and tat-III purified proteins respectively. The molecular weight of the proteins was derived from molecular weight standard proteins electrophoresed on the same gel (Bethesda Research Laboratory, Bethesda, MD). HN, HH, and HM refer to human sera and represent a healthy, normal, not-at-risk patient; healthy homosexuals; and a healthy mother of a child with AIDS. AIDS and ARC stand for sera obtained from patients with the AIDS syndrome and from patients with AIDS-related complex.

sera from uninfected individuals reacted with the recombinant 18Kd sor protein. This reactivity was specific for the recombinant protein, since a protein of similar size is not detected in the control bacterial lysate (Fig 4, lanes 1 and 2). Similarly, the specific antiserum obtained from a rabbit immunized with the purified protein reacted with the recombinant sor protein (lane 4), while no reaction was observed in the total bacterial lysate (lane 3). The sor protein used in these studies is a chimeric protein that contains at the amino terminus 13 amino acids derived from the ω II gene of the vector.¹² To rule out that the reactivity of the human sera was directed against vector epitopes rather than sor epitopes, we tested the reactivity of the same sera against another chimeric protein expressed in the same vector containing 27% of the coding sequences of the HTLV type I envelope gene p21E.²⁴ Figure 4, lanes 5 and 6, shows that a human serum positive for the recombinant sor protein does not recognize the p21 E recombinant HTLV-I chimeric protein, while a

serum obtained from a patient with adult T cell leukemia does. Thus, the reactivity of human sera from uninfected individuals seems to be directed against the antigenic determinants of the recombinant sor protein.

DISCUSSION

All the known proteins encoded by HTLV-III are immunogenic in vivo, but the spectrum of antibodies that they

Fig 3. The spectrum of natural antibodies in patients' sera is expressed as a percentage of total patients analyzed for each antigen, which is represented on the Y axis. The legend for each antigen is reported in the right upper part of the figure.

Fig 4. Total cell lysate from bacteria expressing the sor protein (lanes 2 and 4) and from control bacteria (lanes 1 and 3) were analyzed by Western blot using a human serum from an uninfected individual (lanes 1 and 2) and a rabbit antiserum raised against the recombinant sor protein (lanes 3 and 4). A Western blot against the purified recombinant protein containing the antigenic determinants of the HTLV-I p21E (lanes 5 and 6) was obtained with the same human serum used in lanes 1 and 2 (lane 5) and with a serum from a patient with adult T cell leukemia (lane 6).

elicit in infected individuals does not seem to correlate with disease stages as they are currently described. We noticed that as infected individuals progressed toward AIDS, they tended to acquire antibodies to all the HTLV-III antigens studied (data not shown). This finding may simply reflect continual expression of the virus in vivo with a greater likelihood of exposure to each antigen with increasing time after infection. Fluctuations in antibody prevalence were observed with stage of disease, particularly with the *sor* and *tat*-III proteins, although the differences observed did not yield statistically significant correlations. These varying prevalences may result from different levels of circulating antigens with disease progression and immune complex formation, leading to lessened detection of serum antibodies. More extensive studies would be necessary to determine whether the observed fluctuations have underlying biologic significance. Direct analysis for circulating immune complexes or complexes trapped in lymph nodes would be informative. It is remarkable that the immune response against all HTLV-III antigens in AIDS patients seems to be comparable to that of the healthy at-risk patients, despite the high degree of immune system failure observed in the former group. Our data suggest that it may be necessary to investigate individuals very soon after viral infection to determine whether sequential exposure to HTLV-III antigens is correlated with laboratory or clinical manifestations of AIDS. In this regard we analyzed sera of three patients at risk who were virus positive, seronegative for antibodies against the HTLV-III envelope and *gag* proteins and who subsequently seroconverted. Their sera were negative for the 3'orf, *sor*,

and *tat*-III before the time of seroconversion, suggesting that these proteins might not be useful in the diagnosis of the early phase of infection. More serum samples from this kind of patient should be studied before a definitive conclusion on this point can be reached. Our analysis has shown that of the five HTLV-III antigens studied, the most immunogenic one appears to be the gp41 transmembrane protein. As the major envelope protein gp120 also appears to be highly immunogenic,²³ it would be useful to include it in screening procedures when the purified protein becomes available. Obviously the use of a combination of bacterially synthesized antigens for large scale antibody testing not only could increase the sensitivity of antibody detection but could also eliminate the problem of obtaining false-positive results due to contamination of virus preparations with human antigens. In this regard it should be noticed that the *sor* protein should not be used in the antibody screening procedure because it could be the cause of false-positive results. In fact, we have shown that some human sera from not-at-risk, uninfected individuals have antibodies that react with the *sor* antigenic determinants. We believe that this reactivity may be due to crossreactive determinants in either endogenous or exogenous proteins that elicit an immune response in humans.

ACKNOWLEDGMENT

We are very grateful to Drs J. Ghayeb, T. Papas, C. Debouckh, and K. Samuel for providing purified proteins and to Dr Robert C. Gallo for his support. We also thank Dee Goodrich for editorial assistance.

Formation and Functioning of the Factor IXa-VIII Complex on the Surface of Endothelial Cells

By Katalin Váradi and Susan Elödi

The formation and functioning of the factor X activating complex on the surface of cultured human venous endothelial cells (HVEC) were investigated. To the HVEC monolayer human factors IXa, VIII, X, CaCl_2 , and S-2222 were added, and a gradually increasing activation of factor X was observed. The maximum activity of 88 nmol/L Xa/min was reached after a 12-minute lag phase. In the presence of thrombin-activated factor VIII (VIII_t) the same maximum activity developed in eight minutes, which suggests that VIII_t accelerates the formation of the IXa-VIII complex but does not influence its factor X-activating potential. Anti-VIII IgG did not affect the activity of the full-fledged

complex. When anti-VIII IgG was added to the reaction mixture before factor VIII or during the lag phase of the reaction, it induced a concentration-dependent decrease of factor X activation. These results indicate that endothelial cells provide a binding surface for the IXa-VIII complex and that in the HVEC-bound complex factor VIII is protected from the effect of a specific antibody. However, the relatively slow development of the maximum activity indicates that HVEC only partially satisfy the surface criteria for the optimal assembly of the IXa-VIII complex.

© 1987 by Grune & Stratton, Inc.

EVENTS LEADING TO THROMBUS formation are thought to be initiated by damage to the vascular endothelium. The intact endothelial cell lining is generally believed to provide a nonthrombogenic surface for blood.¹ Recently, it became evident that the endothelium cannot be regarded as an inert lining but that the endothelial cells actively contribute to the maintenance of blood fluidity. Endothelial cells synthesize and release prostacyclin,² which inhibits platelet aggregation, as well as plasminogen activator,³ which contributes to the dissolution of fibrin.

Thrombomodulin, an endothelial cell membrane protein, binds thrombin and protein C with high affinity.^{4,5} Protein C activated by thrombin effectively inactivates factors V and VIII⁶; thus it serves as a regulator of coagulation. In contrast to these nonthrombogenic functions, recent data suggest that reactions promoting clot formation may also take place on the surface of intact endothelial cells. Both zymogen and active factors IX and X can attach to the surface of vascular endothelial cells.⁷⁻⁹ Bovine aortic endothelial cells synthesize factor V. In the presence of exogenous factor X and calcium, the formation of the prothrombinase complex and production of thrombin was demonstrated on the surface of bovine aortic endothelial cells.¹⁰

Previously we found that the complex of factor IXa and factor VIII is formed on the surface of activated platelets.¹¹ Complex-bound factors IXa and VIII display novel properties of being resistant to the effect of specific inhibitors.¹²

The aim of this work was to investigate whether endothelial cells could provide an appropriate surface for the formation and functioning of the factor IXa-VIII complex. We observed that, albeit slowly, the IXa-VIII complex was formed and it activated factor X in the presence of intact endothelial cells. In the endothelial cell-bound complex, factor VIII became resistant to the effect of anti-VIII

antibody, similarly to that observed when the complex was formed on the surface of aggregated platelets.

MATERIALS AND METHODS

Coagulation proteins. All clotting factors used in these experiments were prepared from normal human blood. Factor IXa (194 U/mg) was prepared as described earlier.¹³ Factor VIII (26 U/mg) was purified from a therapeutic factor VIII concentrate by Sepharose 4B chromatography according to Van Mourik and Mochtar.¹⁴ Factor X (6 U/mg) was isolated from a prothrombin complex concentrate by dextran-sulphate-Sepharose chromatography.¹⁵ Anti-VIII IgG (210 BU/mg) was prepared from the plasma of a nonhemophilic patient who developed antibody against factor VIII. The IgG₄ fraction was obtained by QAE-Sephadex chromatography¹⁶ and was further purified by the caprylic acid method of Steinbuch and Audran.¹⁷

Human venous endothelial cells. Isolated from the umbilical cord vein, human venous endothelial cells (HVEC) were cultured as described by Jaffe.¹⁸ During the second passage the cells were plated in culture wells with a 16-mm diameter and were allowed to grow to confluence for 24 hours. One well contained approximately 10⁵ cells. HVEC were cultured and kindly provided by the Department of Transplantation Immunology of our institute.

Assay of clotting factors. Factor IXa activity was measured by a one-stage clotting assay as described previously.¹⁹ The activity of factor VIII was measured by a one-stage assay on factor VIII-deficient human plasma and was related to a freeze-dried local plasma standard calibrated for the Second International Standard for factor VIII (73/552 National Institute for Biological Standards and Control, London). The activity of factor Xa was measured with the chromogenic peptide substrate Bz-Ile-Gly-Arg-pNA (S-2222, KABI Diagnostica, Stockholm) and was related to the factor X plasma standard of Immuno AG (Vienna). Russell's viper venom (RVV, Stypven, Burroughs Wellcome Ltd, Beckenham, England) was used for the activation of factor X when preparing the calibration curve for factor Xa assay. The factor VIII inhibitory capacity of the anti-VIII IgG preparation was measured by the Bethesda method and expressed in Bethesda units.²⁰

Protein assay. The protein content of the clotting factor preparations was determined spectrophotometrically by using the absorption coefficients $A_{280}^{1\%}$: 12.3 for factor VIII,²¹ 13.3 for factor IXa,²² and 12.4 for factor X.²³ The protein content of the anti-VIII IgG preparation was measured according to Lowry et al²⁴ by using bovine serum albumin (Miles Laboratory, Elkhart, IN) as a reference.

Experiments with endothelial cells. Confluent cells from the second passage were washed three times with imidazole-buffered saline (IBS), pH 7.2, composed of 5 mmol/L imidazole HCl and 140 mmol/L NaCl. Then, factor IXa (15.5 μg), factor VIII (1.1 units),

factor X (90 μg), 10 mmol/L CaCl_2 , and 1.3 mmol/L S-2222 in IBS were added in a final volume of 750 μL . The assay mixtures were incubated at 37 $^\circ\text{C}$ and tilted at 60-second intervals for mixing. Fifty-microliter aliquots were withdrawn at different time intervals and diluted with ice-cold IBS containing 10% acetic acid to terminate the reaction.

The activation of factor X was followed by measuring the difference in the absorption of the samples at 405 nm. The amount of factor Xa formed was read from a calibration curve obtained by measuring the activation of 50 to 500 nmol/L factor X in the presence of 10 $\mu\text{g}/\text{mL}$ RVV, 40 mmol/L CaCl_2 and 1.3 mmol/L S-2222.

When thrombin-activated factor VIII (VIII_t) was used in the experiments, factor VIII was preincubated at 37 $^\circ\text{C}$ with 0.05 NIH units/mL thrombin (Topostasine, Hoffman-LaRoche, Basel, Switzerland). A tenfold increase in factor VIII activity was reached in one minute, and then an aliquot was added to the reaction mixture in a final concentration of 1 U/mL.

The HVEC-bound reaction was compared with that taking place in the presence of phospholipid (PL). In these experiments, 10 μg PL (Inosithin, Associated Concentrates, Long Island, NY) was added to the reaction mixture instead of HVEC. The amount of PL was optimized for the concentration of clotting factors as described previously.²⁵

Calculations. The best fitting curves for the experimental points and the appropriate time derivatives were calculated and drawn by a microcomputer applying a polynomial regression analysis program.

RESULTS

Time course of factor X activation. The activation of factor X in the presence of confluent HVEC under various conditions is shown in Fig 1. When all components required for the activation of factor X were added to HVEC (Fig 1A, curve a) after a three- to four-minute lag phase, the increase in absorbancy indicated that the activation of factor X had been initiated. After 12 minutes' incubation, the change in absorbancy became proportional to time, thus suggesting

Fig 1. Time course of activation of factor X by the IXa-VIII complex. (A) The activation of factor X was monitored by the increase of absorbancy due to splitting of S-2222 by factor Xa formed in the assay system. Factor Xa was generated in the presence of HVEC, Ca, IXa, and VIII (curve a); HVEC, Ca, IXa and VIII, (curve b); PL, Ca, IXa, and VIII (curve c); and HVEC, Ca, and IXa (curve d). (B) Time derivatives of the experimental curves of Fig 1A showing the kinetics of factor X activation during the assembly of the IXa-VIII complex. Symbols are the same as in (A). For details of the experiments and calculations see Materials and Methods.

that the activation of factor X reached its maximum velocity. When factor VIII was omitted from the reaction mixture (Fig 1A, curve d), factor IXa activated factor X only at a low rate. To exclude the possibility of any nonspecific binding of the investigated factors to the culture wells, all components needed for factor X activation were incubated in empty wells, but in this case activation of factor X was not detected (not shown).

Previously we found that VIII_t in the presence of PL or platelets accelerates the formation of the IXa-VIII complex.^{11,25} Curve b in Fig 1A illustrates that a similar phenomenon occurs when the IXa-VIII complex is formed in the presence of HVEC. The addition of VIII_t to the reaction mixture induced a more rapid increase in absorbancy already at the beginning of the reaction, thus indicating the accelerating effect of VIII_t . However, even with VIII_t , the rate of activation of factor X was less in the presence of HVEC than that measured in the control experiment with PL and factor VIII without thrombin pretreatment (curve c, Fig 1A).

It was assumed that the maximum velocity of factor X activation is reached after the assembly of factors IXa and VIII in the complex. The kinetics of the formation of the IXa-VIII complex are shown in Fig 1B where the velocity of factor X activation in the course of the assembly of the IXa-VIII complex is illustrated. When the complex is formed with untreated factor VIII (Fig 1B, curve a) the maximum activity, ie, the production of 88 nmol/L Xa/min, is reached after 12 minutes' incubation, whereas with VIII_t (Fig 1B, curve b) the maximum activity is measured after eight minutes. The accelerating effect of VIII_t is most pronounced at the beginning of the reaction where a steady increase in the reaction rate is seen. In contrast to this, in the presence of untreated factor VIII, significant activation of factor X does not occur for two minutes. Control experiments carried out with PL suggest that under these conditions PL provides a more favorable surface for the formation of the IXa-VIII complex than do HVEC. With PL preparation, the maximum activity, ie, the production of 110 nmol/L Xa/min, is reached after six minutes (Fig 1B, curve c).

It has to be pointed out that, although VIII_t increased the rate of formation of the IXa-VIII complex, it did not influence the maximum activity of the fully fledged complex. Irrespective of the state of factor VIII, the HVEC-bound complex produced 88 nmol/L Xa/min, ie, about 80% of that measured in the presence of PL.

Effect of anti-VIII IgG on HVEC-bound factor VIII.

The anti-VIII IgG used in our experiments inactivated factor VIII in solution as shown in Fig 2. When the antibody was added to the HVEC-bound complex after development of the maximum activity, the antibody appeared to be ineffective. This phenomenon suggests that the antigen determinants of the complex-bound factor VIII become masked and are not accessible for the specific antibody.

The marked differences observed between antibody-induced inactivation of free and complex-bound factor VIII raised the question whether the complex of factors IXa and VIII could be formed in the presence of anti-VIII IgG. As shown in Fig 3, when the antibody was added to the preincubation system at zero time, ie, at the beginning of

Fig 2. Effect of anti-VIII IgG on the activity of factor VIII and on the HVEC-bound IXa-VIII complex. Change of activity of 1 U/mL factor VIII at 37 °C in the presence of 5 BU/mL (x—x) and of 10 BU/mL (●—●) anti-VIII:C IgG. The activity of the HVEC-bound complex is also shown in the presence of 10 BU/mL anti-VIII IgG (○—○) added when the maximum activity of the IXa-VIII complex developed.

complex formation, the initial rate of factor X activation and the maximum activity of the complex decreased in proportion to the antibody concentration. When the antibody was added to the reaction mixture in the fifth minute of incubation, the inhibitory effect was less pronounced; 60% of the maximum activity developed even after adding 10 BU/mL antibody (Table 1). These data suggest that in the fifth minute of complex formation a part of factor VIII present is already incorporated into the complex and only the free factor VIII is still accessible for the antibody.

DISCUSSION

It is generally accepted that some reactions of the clotting process take place on the membrane of aggregated platelets. Two consecutive enzyme complexes of coagulation, ie, the IXa-VIII and the prothrombinase complex, have been shown to be formed on the membrane of platelets.^{11,26,27} Recent investigations, however, indicate that the platelets are not the only cells that can provide a binding surface for the clotting factors. Bovine factors IX and X bind to bovine aortic endothelial cells with high affinity.⁷ The endothelial cell-bound factor IX can be readily activated by factors XIa and VIIa.⁹ In the case of comparable cell numbers, the prothrom-

5	60	49
11	88	88

binase complex was found to be more efficient on the surface of bovine aortic endothelial cells than in the presence of activated thrombocytes.¹⁰ However, HVEC appear to be less convenient for the binding and functioning of clotting factors than the bovine aortic endothelial cells. The prothrombinase complex, for example, produces thrombin at a considerably lower rate on human venous cells than on bovine aortic cells.¹⁰

Our experiments with HVEC show that in the absence of factor VIII factor IXa produces only 5 nmol/L Xa/min. When factor VIII was present, factor IXa produced 88 nmol/L Xa/min after a ten- to 12-minute lag phase, ie, factor VIII increased the activity of factor IXa about 18-fold. However, the maximum activity of the HVEC-bound IXa-VIII complex does not reach the value of 110 nmol/L Xa/min measured in the presence of PL in control experiments.

Our previous studies indicated that the rate-limiting step in the assembly of the IXa-VIII complex is the binding velocity of factor VIII.²⁸ The present data, however, suggest that the properties of the binding surface also have a marked influence on the rate of assembly of the complex. In the presence of HVEC, ten to 12 minutes was needed for the development of the maximum activity. Although VIII_i shortened this time to eight to nine minutes, this rate of assembly is still considerably slower than that measured previously with platelets and VIII_i, where the maximum activity developed in one minute.¹¹

Previously we found that in the presence of platelets complex-bound factor VIII had become protected from the effect of the specific anti-VIII antibody.¹² A similar protection was described in the case of PL-bound factor VIII.²⁹

Our experiments with HVEC demonstrate that the protection of the surface-bound VIII prevails in the presence of these cells too. In the experiments carried out with platelets, the presence of 2 BU/mL anti-VIII IgG prevented the formation of the IXa-VIII complex.¹² In contrast to this, when the formation of the IXa-VIII complex was investigated on HVEC, 25% and 50% of the maximum activity developed in the presence of 10 and 5 BU/mL anti-VIII IgG, respectively. These results suggest that in spite of the relatively slow assembly of the complex the HVEC offers a more effective protection for factor VIII than the platelet surface.

Although our results and the data of Rodgers and Shuman¹⁰ demonstrate that both the IXa-VIII and the prothrombinase complex are formed in vitro on the surface of endothelial cells, the question arises whether HVEC-bound complexes play a role in physiological coagulation. The rate

Fig 3. Formation of the HVEC-bound IXa-VIII complex in the presence of anti-VIII IgG. Five and 10 BU/mL anti-VIII IgG were added (arrows) to the reaction mixture at 12 minutes (—) or five minutes (---) of incubation and at time 0 (· · · · ·), ie, before the addition of factor VIII. (A) best-fitting curves of three experiments. (B) Time derivatives of experimental curves of (A).

of the assembly of the IXa-VIII complex is considerably slower on HVEC than that we have observed previously on the surface of platelets.¹¹ This indicates that in physiological coagulation platelets probably play a predominant role in providing binding surface for the IXa-VIII complex. If a

conclusion may be drawn for the in vivo processes from the data obtained with cultured cells, then it may be assumed that in the venous circulation the slow formation of the IXa-VIII complex on the surface of intact endothelial cells may contribute to the development of venous thrombosis.

Monoclonal Antibodies to Discrete Regions in α_2 -Plasmin Inhibitor

By Jun Mimuro, Yukiya Koike, Yoshihiko Sumi, and Nobuo Aoki

Three monoclonal antibodies to α_2 -plasmin inhibitor (α_2 PI) were characterized. The first, JTPI-1, was directed against the reactive site of α_2 PI and inhibited antiplasmin activity by interfering with the formation of α_2 PI-plasmin complexes. The avidity of JTPI-1 to the preformed α_2 PI-plasmin complex was markedly lower than that to free α_2 PI, which made this antibody useful for measuring the free α_2 PI in plasma. The second, JTPI-2, recognized an epitope in the C-terminal fragment of α_2 PI (11,000 daltons [11 K]) that was cleaved from α_2 PI by plasmin upon complex formation but remained noncovalently attached to the complex. However, binding of JTPI-2 to α_2 PI was not inhibited by the C-terminal 26-residue peptide containing the plasminogen-

binding site and had no effect on the function of α_2 PI. These data suggested that JTPI-2 recognized an epitope between the C-terminal 26-residue peptide and the reactive site. The third, JTPI-3, bound the α_2 PI-plasmin complex (150 K) as well as α_2 PI. Binding was inhibited by the N-terminal 12-residue peptide of α_2 PI, but factor XIII-catalyzed cross-linking of α_2 PI to fibrin was not inhibited by JTPI-3. These results suggested that the antibody recognized an epitope near the N terminus. These three monoclonal antibodies were useful for analyzing the mechanism of interaction between α_2 PI and plasmin.

THE α_2 PLASMIN INHIBITOR (α_2 PI) is a physiological inhibitor of plasmin¹⁻³ so that it acts as a major inhibitor of fibrinolysis in plasma.^{4,5} It inhibits a physiologically occurring fibrinolytic process that follows fibrin formation, thereby stabilizing hemostatic plugs.⁶ Its congenital deficiency results in a lifelong severe hemorrhagic tendency.⁷ The α_2 PI molecule has three functional domains: the reactive site for plasmin, the plasmin(ogen) or LBS-binding site (complementary to the LBS [lysine-binding site] of plasmin[ogen]), and the cross-linking site for fibrin. These functional properties of α_2 PI have been reviewed recently.⁵ In the present study we have developed monoclonal antibodies to α_2 PI, and the epitopes recognized by these antibodies have been characterized, particularly in reference to the functional domains.

MATERIALS AND METHODS

Purified protein. α_2 PI was purified from human plasma by a previously described method.¹ The concentration was determined spectrophotometrically using $E_{1\text{cm}}^{1\%} = 7.03$ at 280 nm.¹

Native Glu-plasminogen and modified Lys-plasminogen were purified from human plasma by affinity chromatography using lysine-sepharose followed by diethyl aminoethyl Sephadex ion-exchange chromatography as described.⁸ The concentration of plasminogen was determined spectrophotometrically using $E_{1\text{cm}}^{1\%} = 16.8$ at 280 nm.⁹

Human fibrinogen prepared according to the method of Blombäck

and Blombäck¹⁰ was further purified by removing contaminating plasminogen and plasma fibronectin from the preparation with lysine-Sepharose⁸ and gelatin-Sepharose¹¹ respectively. The concentration was determined spectrophotometrically using $E_{1\text{cm}}^{1\%} = 15.1$ at 280 nm, and the coagulatable protein was more than 95%.

Plasmin was prepared by the activation of plasminogen using urokinase-coupled Sepharose 4B as described.¹ Factor XIII was purified from human plasma by the method described by Curtis and Lorand.¹² Factor XIII activity was assayed by the dansylcadaverine incorporation method as described by Lorand et al.¹³ One unit of factor XIII is defined as the activity of factor XIII present in 1 mL of normal pooled standard plasma.

Purification of the α_2 PI-plasmin complex. α_2 PI-plasmin complex was prepared in an α_2 PI excess according to the method of Wiman and Collen.^{14,15} The α_2 PI-plasmin complex was isolated using lysine-Sepharose as described. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of the complex showed protein bands at 150,000 daltons (150 K) and 11 K. The 11-K fragment is the C-terminal fragment of α_2 PI, which was originally observed by Wiman and Collen¹⁵ as an 8-K fragment that was cleaved from α_2 PI upon the α_2 PI-plasmin complex formation but which remained firmly bound to the complex. This fragment could be dissociated from the complex only in the presence of denaturants such as SDS.¹⁵ The α_2 PI-plasmin complex was also prepared by the same method using ¹²⁵I-labeled plasminogen, and the molar concentration of the complex was calculated from the radioactivity of the complex and the specific radioactivity of the original plasminogen used, assuming one-to-one molar complex formation. One $\mu\text{mol/L}$ of the complex was found to have an absorbance value of 0.157 at 280 nm.

Synthetic peptides. The synthetic C-terminal 26-residue peptide of α_2 PI¹⁶ (H-Gly-Asp-Lys-Leu-Phe-Gly-Pro-Asp-Leu-Lys-Leu-Val-Pro-Pro-Met-Glu-Glu-Asp-Tyr-Pro-Gln-Phe-Gly-Ser-Pro-Lys-OH) was a gift from the Research Institute, Daiichi Pharmaceutical Co (Tokyo). The synthetic N-terminal 12-residue peptide of α_2 PI¹⁷ (H-Asn-Gln-Glu-Gln-Val-Ser-Pro-Leu-Thr-Leu-Leu-Lys-OH) was synthesized by solid-phase peptide synthesis using a peptide synthesizer, model 430 A (Applied Biosystems Inc, Foster City, CA).

Reagents for monoclonal antibody production. The mouse myeloma cell line P3U1 was provided by Dr T. Watanabe, Kyushu University, Japan. The following reagents were purchased: Freund's adjuvants, polyethylene glycol 1540, and 2, 6, 10, 14-tetramethyl pentadecane (pristane) from Wako Chemical Co (Osaka, Japan); Dulbecco's modified Eagle's medium from GIBCO (Chagrin Falls, OH); fetal calf serum from Filtron (Victoria, Australia); and

hypoxanthine, aminopterin, thymidine (HAT), gelatine, diisopropylfluorophosphate and bovine serum albumin (BSA) from Sigma Chemical Co (St Louis). Other reagents were from Sigma or Wako, and were analytic grade.

Monoclonal antibody production. Monoclonal antibodies against α_2 PI were produced according to the method of Köhler and Milstein.¹⁸ Four-week-old female BALB/C mice were immunized with human α_2 PI three times. First, 50 μ g in complete Freund's adjuvant was injected intraperitoneally. Second, 50 μ g in incomplete Freund's adjuvant was injected intraperitoneally. Third, 30 μ g in phosphate-buffered saline was injected intravenously. Spleen cells from immunized mice were fused with the mouse myeloma cell lines P3-x63-Ag8-U1 (P3U1) by using 50% polyethylene glycol 1540. The fused cells were cultured in HAT media. Anti- α_2 PI antibody-producing cell lines, screened by an enzyme-linked immunosorbent assay (ELISA), were recloned by limiting dilution. Finally, each clone was injected intraperitoneally into BALB/C mice that were pretreated with pristane. Monoclonal antibodies were purified from the ascites fluid of the mice by affinity chromatography using protein A-sepharose CL 4B (Pharmacia Fine Chemicals, Tokyo) according to the standard method.¹⁹

ELISA. ELISA was performed essentially according to previously described methods²⁰ and was used to screen antibody production of fused cells. α_2 PI (5 μ g/mL in 0.02 mol/L sodium phosphate and 0.135 mol/L NaCl, pH 7.4; phosphate-buffered saline)-coated polyvinylchloride microtiter plates (Titertek, Zwanenburg, The Netherlands) were first incubated with antibody sources at 37 °C for two hours and then with alkaline phosphatase-conjugated antimouse IgG rabbit IgG (1 μ g/mL) (Kikegaard & Perry Laboratory, Gaithersburg, MD) at 37 °C for two hours. The hydrolysis of p-nitrophenyl phosphate (1 mg/mL in 97 mmol/L diethanolamine, 0.49 mmol/L MgCl₂, pH 9.8) by microtiter plate-bound alkaline phosphatase was monitored at 25 °C using the ETY96 ELISA analyzer (Toko-Sokki, Tokyo). After each step the plates were washed with phosphate-buffered saline containing 1% BSA and 0.05% Tween 20 (washing buffer) five times. ELISA was also used to assay α_2 PI or the α_2 PI-plasmin complex in a purified system as follows. Monoclonal antibody (solid-phase antibody, 10 μ g/mL, in 50 mmol/L carbonate buffer, pH 9.6)-coated microtiter plates were incubated with various concentrations of α_2 PI or the α_2 PI-plasmin complex in washing buffer at 37 °C for four hours followed by alkaline phosphatase-conjugated monoclonal antibody (liquid-phase antibody) at 10 nmol/L in washing buffer at 37 °C for four hours. The enzymatic activity of each well was monitored as was described. The α_2 PI-plasmin complex in plasma was assayed using a modification of the method of Harpel.²¹ Immunopurified polyclonal rabbit antibody to human plasminogen was used as a solid-phase antibody (20 μ g/mL) and the alkaline phosphatase-conjugated monoclonal antibody JTPI-2 as a liquid-phase antibody (10 nmol/L). A standard curve was constructed using purified α_2 PI-plasmin complex.

Radioiodination of protein. α_2 PI, plasminogen, and monoclonal antibodies were radioiodinated using immobilized lactoperoxidase glucose oxidase (Enzymobead, Bio-Rad Laboratories, Richmond, CA) and Na ¹²⁵I (17 Ci/mg) (New England Nuclear, Boston). The concentration of radiolabeled protein was determined spectrophotometrically. The antiplasmin activity of radiolabeled α_2 PI was measured as will be described in the section entitled "Effect of monoclonal antibodies on antiplasmin activity of α_2 PI" and was the same as that of native α_2 PI.

Binding study of monoclonal antibodies. The avidities of ¹²⁵I-labeled antibodies for α_2 PI and α_2 PI-plasmin complexes were assessed by a solid-phase assay previously described by Frankel and Gerhard.²² α_2 PI or the α_2 PI-plasmin complex was dissolved to a concentration of 100 nmol/L in phosphate-buffered saline. Each

well of the polyvinylchloride microtiter plate was coated with 100 μ L of α_2 PI or the α_2 PI-plasmin complex and was incubated at 4 °C for 16 hours. The plate was washed five times with washing buffer. Various concentrations of ¹²⁵I-labeled antibodies were dissolved in washing buffer, 100 μ L of each antibody solution was added to each well, and the plate was allowed to incubate at 37 °C for four hours. After the plate was again washed with washing buffer five times, the wells were removed from the plate, and each well was subjected to γ counting using a γ counter (Packard Institute, Downers Grove, IL). The radioactivities of BSA-coated wells incubated with the same concentrations of ¹²⁵I-labeled antibodies were subtracted from the radioactivities of α_2 PI- or α_2 PI-plasmin complex-coated wells. The results for duplicate wells were averaged. The radioactivity found in each well was converted to the concentration of antibody bound. The concentration of free antibody was calculated from the total radioactivity of the antibody solution added to the well and the radioactivity of the antibody bound to the well. The dissociation constants of antibodies to α_2 PI or the α_2 PI-plasmin complex were calculated from a modified Scatchard plot according to the method of Frankel and Gerhard.²² The Sipsian heterogeneity constant for each monoclonal antibody to α_2 PI was also calculated as described.²²

Agarose isoelectric focusing. Isoelectric focusing of monoclonal antibodies was performed using Multiphor (LKB, Bromma, Sweden) at 4 °C over a pH range of 3.5 to 9.0 with 2.5% ampholine (LKB) according to the method described in the instructions of the manufacturer. After electrophoresis, the gel was fixed, dried, and stained with Coomassie blue.

SDS-PAGE. SDS-PAGE on a slab gel was carried out using a gradient separating gel of acrylamide (7.5% to 15%) containing 0.1% SDS and a stacking gel of 4% acrylamide containing 0.1% SDS according to the method of Laemmli.²³ Molecular weight standards of myosin (200 K), phosphorylase b (94 K), BSA (67 K), ovalbumin (45 K), carbonic anhydrase (30 K), trypsin inhibitor (22 K), cytochrome c (12.5 K), and aprotinin (6.5 K) were obtained from Bio-Rad Laboratories and Boehringer Mannheim GmbH (Mannheim, West Germany).

Immunoblotting technique. After separation by SDS-PAGE, the proteins were electrophoretically (50 V for 1.5 hours) transferred to nitrocellulose membranes (Bio-Rad) essentially as described²⁴ using an electroblot apparatus (Marysol Industry Co, Tokyo) equipped with a cooling system (Multitemp, LKB). After transferring, the nitrocellulose sheets were incubated in Tris buffer (0.02 mol/L Tris, 0.5 mol/L NaCl, pH 7.5) containing 3% (wt/vol) gelatin at 25 °C for two hours, washed twice with Tris buffer containing 0.05% Tween 20, and incubated in Tris buffer containing 1% (wt/vol) gelatin, 0.05% Tween 20, and monoclonal antibodies (500 ng/mL) at 25 °C for 16 hours. The nitrocellulose sheets were then washed with Tris buffer containing 0.05% Tween 20, incubated with horseradish peroxidase-conjugated antimouse IgG goat antibody (Bio-Rad) dissolved in Tris buffer containing 1% gelatin and 0.05% Tween 20 at 25 °C for two hours, washed twice with Tris buffer containing 0.05% Tween 20, and subjected to color development using 4-chloro-1-naphthol (Bio-Rad).

Radioautography. After SDS-PAGE of the samples containing radioiodinated proteins, the slab gel was dried and then exposed to x-ray film (Lo-dose film, E.I. Du Pont de Nemours & Co, Wilmington, DE) in the presence of intensifying screens (Lo-Dose/2 mammography intensifying screen, Du Pont) for 48 hours at -70 °C.

Effect of monoclonal antibodies on antiplasmin activity of α_2 PI. α_2 PI was mixed and incubated with various concentrations of monoclonal antibodies or buffered saline at 37 °C for 30 minutes and then at 4 °C for 24 hours. Subsequently, 100 μ L of the α_2 PI (12.5 nmol/L) and 100 μ L of plasmin (25 nmol/L) were mixed in 500 μ L of Tris-buffered saline (0.05 mol/L Tris, 0.1 mol/L NaCl, pH 7.4). After incubation for zero, 30 seconds, 2 minutes, 5 minutes,

and 30 minutes, 500 μ L of S-2251 (plasmin-specific tripeptide substrate H-D-Val-Leu-Lys-*p*-nitroanilide, Daiichi Pure Chemicals, Tokyo) (2 mmol/L) was added, and the subsequent hydrolysis of S-2251 by residual plasmin was monitored using a DU-8 spectrophotometer (Beckman Instruments, Fullerton, CA).^{25,26} The antiplasmin activity of α_2 PI preincubated with monoclonal antibody was expressed as a percentage of that of α_2 PI without monoclonal antibody using the standard curve constructed from the activities of various concentrations of α_2 PI.

Effect of monoclonal antibodies on cross-linking of α_2 PI to fibrin. ¹²⁵I-labeled α_2 PI was incubated with various concentrations of monoclonal antibodies or buffered saline at 37 °C for 30 minutes and then at 4 °C for 24 hours. Subsequently, 10 μ L of the ¹²⁵I-labeled α_2 PI (700 μ g/mL), 10 μ L of fibrinogen (20 mg/mL), 10 μ L of factor XIII (5 U/mL), 20 μ L of thrombin (5 U/mL), and 50 μ L of Tris-buffered saline containing 5 mmol/L CaCl₂, 2% BSA, and 20 U/mL aprotinin (Mochida Pharmaceuticals, Tokyo) were mixed and incubated at 37 °C. Ten or 30 minutes later, the clots were squeezed with a stick and washed three times with Tris-buffered saline containing 2% BSA, 5 mmol/L EDTA, and aprotinin (10 U/mL).²⁷ The washed clots were then redissolved by heating at 100 °C in 8 mol/L urea, 2% SDS, and 10% β -mercaptoethanol. From the radioactivity of the redissolved clot and the total radioactivity of each initial reaction mixture, the percentage of α_2 PI cross-linked to fibrin was calculated.

Effect of monoclonal antibodies on the inhibition of plasminogen adsorption to fibrin by α_2 PI. α_2 PI was incubated with various concentrations of monoclonal antibodies or buffered saline at 37 °C for 30 minutes and then at 4 °C for 24 hours. Subsequently, 10 μ L of the α_2 PI (700 μ g/mL), 10 μ L of ¹²⁵I-labeled Lys-plasminogen (2 mg/mL), 10 μ L of fibrinogen (20 mg/mL), 20 μ L of thrombin (5 U/mL), and Tris-buffered saline containing 2% BSA, 2 mmol/L EDTA, and 20 U/mL aprotinin were mixed and incubated at 37 °C for two hours. Clots were squeezed using a stick and washed three times with Tris-buffered saline containing 2% BSA, 2 mmol/L EDTA, and aprotinin (10 U/mL). The clots were redissolved by heating at 100 °C in 8 mol/L urea, 2% SDS, and 10% β -mercaptoethanol. The adsorption of ¹²⁵I-labeled plasminogen to fibrin was calculated from the initial radioactivity and the radioactivity of the redissolved clot.²⁸ The degrees of adsorption of ¹²⁵I-labeled plasminogen at various concentrations of α_2 PI preincubated with monoclonal antibodies were compared with those without monoclonal antibodies.

Effect of synthetic peptides on the binding of α_2 PI to monoclonal antibodies. Polyvinylchloride microtiter plates were coated with monoclonal antibody at 10 μ g/mL in 0.05 mol/L carbonate buffer, pH 9.6, at 4 °C and were further incubated with 0.05 mol/L carbonate buffer, pH 9.6, containing 1% BSA for two hours at 37 °C. The plates were washed with washing buffer five times. ¹²⁵I-labeled α_2 PI at the concentration of the half-saturated binding level for each antibody was mixed with various concentrations of the C-terminal or N-terminal peptide and was allowed to incubate in antibody-coated wells at 37 °C for four hours. After washing, the wells were removed from the plates and were subjected to γ counting. The binding of ¹²⁵I- α_2 PI with various concentrations of the peptides was expressed as the percentage of that without the peptides.

RESULTS

Hybridomas producing monoclonal antibodies against α_2 PI were isolated. After limiting dilution, 26 clones were shown to produce antibodies capable of binding to α_2 PI. Three clones were selected for further investigation and were named JTPI-1, JTPI-2, and JTPI-3.

The purified monoclonal antibodies from JTPI-1, JTPI-2, and JTPI-3 each showed a single band (isoelectric point) upon isoelectric focusing (Fig 1). The class and subclass of each monoclonal antibody were determined by an immunodiffusion test using rabbit antibodies specific for murine immunoglobulins. The subclass of heavy chain and class of light chain for JTPI-1, JTPI-2, and JTPI-3 were γ 1 $\cdot$ κ , γ 2a $\cdot$ κ , and γ 2b $\cdot$ κ , respectively.

The binding sites of the monoclonal antibodies to α_2 PI were investigated by immunoblotting (Fig 2). JTPI-1 bound α_2 PI (67 K) but was not shown to bind the α_2 PI-plasmin complex (150 K) or the α_2 PI fragment (11 K) that was cleaved from α_2 PI upon complex formation. JTPI-2 bound α_2 PI (67 K) and the α_2 PI fragment (11 K). It did not bind the α_2 PI-plasmin complex (150 K). JTPI-3 bound α_2 PI (67 K) and the α_2 PI-plasmin complex (150 K). It did not bind the α_2 PI fragment (11 K). When the α_2 PI-plasmin complex was incubated with a catalytic amount of plasmin, the complex (150 K) gradually lost its ability to bind JTPI-3 (Fig 3B), although any change in its molecular weight was not apparent (Fig 3A).

The effect of monoclonal antibodies on the antiplasmin activity of α_2 PI was studied. The presence of a molar excess of JTPI-1 totally inhibited the antiplasmin activity of α_2 PI, whereas JTPI-2 and JTPI-3 did not inhibit the antiplasmin activity of α_2 PI at all (Fig 4). A half-maximum inhibition of the antiplasmin activity of α_2 PI by JTPI-1 was obtained at the molar ratio (antibody: α_2 PI) of 0.3 (Fig 5), whereas neither JTPI-2 nor JTPI-3 showed any inhibition of the antiplasmin activity of α_2 PI even at a molar ratio of 100 (Fig 5).

During the inhibition of plasmin by α_2 PI, α_2 PI reacts with plasmin to form an enzymatically inactive complex. This

Fig 1. Isoelectric focusing of purified monoclonal antibodies. Twenty micrograms of each monoclonal antibody was subjected to agarose isoelectric focusing at 4 °C on a 3.5- to 9.0-pH gradient as described in Materials and Methods. A, B and C correspond to the antibodies JTP-1, -2, and -3 respectively.

Fig 2. Immunoblotting of α_2 PI and the α_2 PI-plasmin complex using monoclonal antibodies to α_2 PI. Two hundred nanograms of α_2 PI (lane 1) or 400 ng of the α_2 PI-plasmin complex (lane 2) were electrophoresed without reduction by SDS-PAGE on a slab gel with gradient (7.5% to 15%) acrylamide and 0.1% SDS, and the proteins were transferred to nitrocellulose membrane. Strips of the membrane were incubated with the respective monoclonal antibodies JTPI-1 (A), JTPI-2 (B), and JTPI-3 (C). The strips were then washed and incubated with peroxidase-conjugated anti-mouse IgG goat antibody, and color was developed with 4-chloro-1-naphthol as described in Materials and Methods. Arrow 1, α_2 PI-plasmin complex (150 K); arrow 2 α_2 PI (67 K); arrow 3, α_2 PI fragment (11 K). On the left is a molecular weight calibration scale constructed using molecular weight standards.

Fig 3. Immunoblotting of the α_2 PI-plasmin complex undergoing plasminic degradation. A quantity of 1 μ mol/L of the α_2 PI-plasmin complex was incubated with 20 nmol/L plasmin in Tris-buffered saline at 37 °C. After incubation for 2, 30, 60, and 120 min, 10- μ L aliquots were removed. The samples were subjected to SDS-PAGE (A) followed by immunoblotting using antibody JTPI-3 (B) as described in Fig 2.

Fig 4. Effects of monoclonal antibodies on the antiplasmin activity of α_2 PI. One hundred microliters of α_2 PI (12.5 nmol/L) preincubated with monoclonal antibodies (125 nmol/L) and 100 μ L of plasmin (25 nmol/L) were mixed in 500 μ L of Tris-buffered saline and incubated at 25 °C. After various incubation periods, the residual plasmin activity was assayed as described in Materials and Methods. The amidolysis activities of plasmin without α_2 PI ($\square$), plasmin with α_2 PI ($\circ$), plasmin with α_2 PI preincubated with JTPI-1 ($\bullet$), and plasmin with α_2 PI preincubated with JTPI-2 or JTPI-3 ($\blacksquare$) were plotted.

complex formation was observed by radioautography after SDS-PAGE using radioactive α_2 PI. This ^{125} I- α_2 PI-plasmin complex (Fig 6, lane 2) gave rise to radioactive zones in the gel corresponding to the complex (150 K), a smear between the complex (150 K) and the modified α_2 PI (55 K), and modified α_2 PI (55 K). These zones were caused by dissociation of α_2 PI from the complex during electrophoresis. Complex formation was not seen when α_2 PI was preincubated with a molar excess of JTPI-1 (Fig 6). When complex formation was inhibited by JTPI-1 α_2 PI (67 K) was degraded to a 60-K molecule by the free unreacted plasmin (Fig 6). The binding of this degraded α_2 PI to monoclonal antibodies was examined by immunoblotting. The immunoblotting showed binding of the degraded α_2 PI to JTPI-3 but did not show any binding to JTPI-2 (Fig 7).

The influence of monoclonal antibodies on the cross-linking of α_2 PI to fibrin and on the inhibitory activity of α_2 PI for plasminogen adsorption to fibrin was assessed. JTPI-1, JTPI-2, and JTPI-3 had no influence on these functions of α_2 PI even when the antibodies were used in a tenfold molar

Fig 5. Effects of various concentrations of monoclonal antibodies on the antiplasmin activity of α_2 PI. The antiplasmin activity of α_2 PI preincubated with various concentrations of monoclonal antibody JTPI-1 ($\bullet$), JTPI-2, or -3 ($\blacksquare$) was assessed at zero-time incubation with plasmin as in Fig 4 and expressed as a percentage of that of α_2 PI without antibody. The activities of α_2 PI were plotted against the molar ratios of monoclonal antibodies to α_2 PI plotted on a semilogarithmic scale.

Fig 6. Radioautogram of the reaction products of plasmin and ^{125}I - $\alpha_2\text{PI}$ preincubated with monoclonal antibody JTPI-1. Twenty-five microliters of ^{125}I - $\alpha_2\text{PI}$ (2 $\mu\text{mol/L}$) preincubated with various concentrations of the antibody in Tris-buffered saline was mixed with 25 μL of plasmin (2 $\mu\text{mol/L}$). After five minutes' incubation at 37 $^\circ\text{C}$, the samples were mixed with 0.125 mol/L Tris, pH 6.8, containing 2% SDS and heated at 100 $^\circ\text{C}$ for two minutes. The samples were subjected to SDS-PAGE and analyzed by radioautography as described in Materials and Methods. The first column (extreme left), native $\alpha_2\text{PI}$; the second column, $\alpha_2\text{PI}$ reacted with plasmin. From the third column to the right, $\alpha_2\text{PI}$ preincubated with the antibody JTPI-1 in various molar ratios of JTPI-1/ $\alpha_2\text{PI}$ as indicated was reacted with plasmin. Arrow 1, $\alpha_2\text{PI}$ -plasmin complex; arrow 2, native $\alpha_2\text{PI}$; arrow 3, degraded $\alpha_2\text{PI}$. On the left is a molecular weight calibration scale constructed using molecular weight standards.

excess over $\alpha_2\text{PI}$. Furthermore, a synthetic C-terminal peptide of $\alpha_2\text{PI}$ (26 residues), which contains the plasmin(ogen) or LBS-binding site of $\alpha_2\text{PI}$, did not inhibit the binding of ^{125}I -labeled $\alpha_2\text{PI}$ to each monoclonal antibody-coated microtiter plate (Fig 8). However, the N-terminal peptide (12 residues), which contains the cross-linking site, inhibited the binding of ^{125}I -labeled $\alpha_2\text{PI}$ to JTPI-3-coated microtiter plates (Fig 8).

Dissociation constants (KD) for monoclonal antibodies to $\alpha_2\text{PI}$ or the $\alpha_2\text{PI}$ -plasmin complex were assessed to estimate the avidity of these monoclonal antibodies (summarized in Table 1). The dissociation constants for $\alpha_2\text{PI}$ binding to all three monoclonals were the same, 1.54 to 2.89 nmol/L. The KDs for JTPI-2 and JTPI-3 binding to the $\alpha_2\text{PI}$ -plasmin complex were also 2.59 to 3.17 nmol/L. However, the KD for JTPI-1 binding to the $\alpha_2\text{PI}$ -plasmin complex was markedly higher, 10.6 nmol/L. Sipsian heterogeneity constants²² for JTPI-1, JTPI-2, and JTPI-3 were essentially equal and were 1.10, 0.99, and 0.99, respectively.

ELISA of $\alpha_2\text{PI}$ and the $\alpha_2\text{PI}$ -plasmin complex was performed using JTPI-1 as a solid-phase antibody and alkaline phosphatase-conjugated JTPI-2 as a liquid-phase antibody. As shown in Fig 9, the enzymatic activities of plates increased proportionally to the $\alpha_2\text{PI}$ concentration from 0.8 to 3 nmol/L. But when the $\alpha_2\text{PI}$ -plasmin complex was assayed in the same way, no enzymatic activities were

Fig 7. Immunoblotting of the reaction products of plasmin and $\alpha_2\text{PI}$ preincubated with monoclonal antibody JTPI-1. Lane 1 contains control native $\alpha_2\text{PI}$ only. In lane 2, $\alpha_2\text{PI}$ preincubated with JTPI-1 at the molar ratio (JTPI-1/ $\alpha_2\text{PI}$) of 1 was reacted with plasmin and subjected to SDS-PAGE as in Fig 6. Proteins transferred to nitrocellulose sheets were reacted with JTPI-2 (A), JTPI-3 (B), or Tris-buffered saline (C) followed by incubation with enzyme-conjugated antimouse IgG goat antibody and color development as described in Materials and Methods. Arrow 1, native $\alpha_2\text{PI}$; arrow 2, degraded $\alpha_2\text{PI}$. The multiple bands seen in upper portions of lane 2 were plasmin-digested monoclonal antibody JTPI-1 that was used for preincubation of $\alpha_2\text{PI}$ and reacted with enzyme-conjugated antimouse IgG antibody. On the left is a molecular weight calibration scale constructed using molecular weight standards.

detected up to 5 nmol/L. The influence of the $\alpha_2\text{PI}$ -plasmin complex on ELISA of $\alpha_2\text{PI}$ was investigated. When a mixture of a fixed concentration of $\alpha_2\text{PI}$ (2 nmol/L) and various concentrations of the $\alpha_2\text{PI}$ -plasmin complex was assayed by ELISA in the same way, no significant increase in enzymatic activity caused by the presence of the complex was detected until the concentration of the complex was increased up to more than 5 nmol/L (Fig 10).

Fig 8. Effects of the synthetic peptides on the binding of monoclonal antibodies to $\alpha_2\text{PI}$. ^{125}I - $\alpha_2\text{PI}$ at the half-saturated level with various concentrations of synthetic C-terminal or N-terminal peptide was added to antibody-coated wells, and the plates were allowed to incubate at 37 $^\circ\text{C}$ for four hours. After washing, the wells were removed from the plates and were subjected to γ counting. Binding of ^{125}I - $\alpha_2\text{PI}$ to antibody-coated wells in the presence of the C-terminal peptide (JTPI-1 [●], JTPI-2 [■], JTPI-3 [▲]) or to antibody-coated wells in the presence of the N-terminal peptide (JTPI-1 [○], JTPI-2 [□], JTPI-3 [△]) was expressed as a percentage of that in the absence of the peptide and plotted against the molar ratios of the peptide to $\alpha_2\text{PI}$ plotted on a semilogarithmic scale.

Table 1. KD and Heterogeneity Constant (α)

	α_2 PI		α_2 PI-Plasmin
	KD (mol/L)	α	KD (mol/L)
JTPI-1	2.18×10^{-9}	1.10	1.06×10^{-8}
JTPI-2	2.89×10^{-9}	0.99	3.17×10^{-9}
JTPI-3	1.54×10^{-9}	0.99	2.59×10^{-9}

The KD values for monoclonal antibodies to α_2 PI or the α_2 PI-plasmin complex and Sipsian heterogeneity constants were calculated as described in Materials and Methods.

Concentrations of α_2 PI and the α_2 PI-plasmin complex in urokinase-treated plasma were assayed by ELISA using various antibodies for the solid-phase antibody (Fig 11). The concentration of the α_2 PI-plasmin complex (measured by ELISA using antiplasminogen for the solid-phase antibody) increased upon the addition of urokinase to the plasma, whereas the concentration of free α_2 PI (measured by ELISA using JTPI-1 for the solid-phase antibody) decreased. The total amount of α_2 PI (free α_2 PI plus the α_2 PI-plasmin complex) remained constant ($0.93 \pm 0.02 \mu\text{mol/L}$). When the experiment was repeated using JTPI-3 for the ELISA solid-phase antibody, the amount of α_2 PI detected (JTPI-3 detects free α_2 PI and the α_2 PI-plasmin complex) remained unchanged upon urokinase treatment.

DISCUSSION

The plasmin(ogen) molecule has specific sites where it noncovalently binds to α_2 PI or fibrin. The sites are called LBS. Their complementary site in α_2 PI could be called the LBS binding site and is located in the region close to the C-terminal end.¹⁶ When α_2 PI inhibits plasmin, the initial reaction involves the binding of the LBS of plasmin to the LBS binding site of α_2 PI. This reaction is reversible. Then, a firm covalent bond is formed between the active-site serine residue of plasmin and the reactive-site leucine residue of α_2 PI¹⁵ to generate the α_2 PI-plasmin complex. Upon complex formation, a C-terminal fragment, which is shown in the present study to be 11 K, is cleaved from α_2 PI but remains noncovalently bound to the complex.¹⁵ The LBS binding site of α_2 PI not only acts during inhibition of plasmin but also inhibits adsorption of plasminogen to fibrin by competing with fibrin for plasminogen binding. Inhibition of plasminogen adsorption to fibrin retards the initiation of the fibrino-

Fig 9. ELISA of α_2 PI and the α_2 PI-plasmin complex. α_2 PI (○) or the α_2 PI-plasmin complex (●) was assayed by ELISA using JTPI-1 for the solid-phase antibody and alkaline phosphatase-conjugated JTPI-2 for the liquid-phase antibody as described in Materials and Methods. The concentrations of α_2 PI or the complex are on the abscissa, and the enzyme activity is on the ordinate.

Fig 10. Influence of the α_2 PI-plasmin complex on ELISA of α_2 PI. Mixtures of 2 nmol/L of α_2 PI and various concentrations of the α_2 PI-plasmin complex were subjected to ELISA as in Fig 9. The concentrations of the complex are on the abscissa, and the enzyme activity is on the ordinate.

lytic process.⁶ On the other hand, α_2 PI itself binds to fibrin during blood coagulation when activated coagulation factor XIII (transglutaminase) catalyzes a cross-linking reaction between α_2 PI and the α chain of fibrin.^{27,29} Studies have revealed that fibrin is mainly protected from plasmin attack by α_2 PI cross-linked to the α chain of fibrin³⁰ during the physiologically occurring fibrinolytic process. Thus, α_2 PI has three functional domains, the reactive site, the LBS binding site, and the cross-linking site. The reactive site is in the C-terminal region of α_2 PI.¹⁵ The LBS binding site is close to the C-terminal end and is contained in the 11-K C-terminal fragment.¹⁶ The cross-linking site is the glutamine located in the second position from the N-terminal end.²⁹ In the present study, we have developed monoclonal antibodies to α_2 PI and have studied the epitopes recognized by these antibodies in relation to the functional domains of α_2 PI.

From 26 clones that produced anti- α_2 PI antibodies, three clones were selected and were named JTPI-1, JTPI-2, and JTPI-3. Each antibody showed a single isoelectric point (Fig 1) and consisted of one subclass of heavy chain and one class

Fig 11. Assay of α_2 PI and the α_2 PI-plasmin complex in plasma. Various concentrations of urokinase were added to citrated plasma in vitro. After a one-hour incubation at 37 °C, aprotinin (115 U/mL) and diisopropyl fluorophosphate (1 mmol/L) were added to the plasma. Then the plasma was diluted 400-fold in washing buffer and assayed for α_2 PI and the α_2 PI-plasmin complex by ELISA as described in Materials and Methods. α_2 PI assayed using JTPI-1 as a solid-phase antibody, ○; α_2 PI assayed using JTPI-3 as a solid-phase antibody, △; α_2 PI-plasmin complex assayed using polyclonal antiplasminogen antibody as a solid-phase antibody, ●. Alkaline phosphatase-conjugated JTPI-2 was used as a liquid-phase antibody. Each point represents the mean $\pm$ SE of triplicate determinations.

of light chain. These data in addition to the Sipsian heterogeneity constants being approximately equal to 1 (Table 1) demonstrate the monoclonality of each antibody.

When the binding site of JTPI-1 was analyzed by immunoblotting, JTPI-1 bound native α_2 PI (67 K) but did not show binding to either the α_2 PI-plasmin complex (150 K) or the C-terminal fragment (11 K). When the binding of radiolabeled antibodies to solid-phase α_2 PI or α_2 PI-plasmin complex was analyzed, JTPI-1 was shown to bind the α_2 PI-plasmin complex but with a markedly lower avidity than that for α_2 PI alone; KD for the complex was five times higher than that for α_2 PI alone (Table 1). Since JTPI-1 completely inhibits the antiplasmin activity of α_2 PI (Figs 4 and 5) by interfering with the formation of α_2 PI-plasmin complexes (Fig 6), the epitope recognized by this antibody must be located either in the reactive site or in the region very close to the reactive site. Although JTPI-1 inhibits complex formation by blocking the reactive site of α_2 PI, the epitope for JTPI-1 on preformed α_2 PI-plasmin complexes remains available but has a markedly reduced affinity (increased KD value) for the antibody (Table 1). The increase in the KD value of JTPI-1 caused by α_2 PI-plasmin complex formation suggests that conformational changes occurred in the epitope upon complex formation or that the plasmin molecule bound to α_2 PI became a steric hindrance, thus preventing access of the antibody to the epitope.

When the ^{125} I- α_2 PI plasmin complex was analyzed by SDS-PAGE (Fig 6), it gave rise to radioactive zones in the gel corresponding to the complex (150 K), a smear (55 to 150 K), and the modified α_2 PI (55 K). These zones were thought to be caused by dissociation of the complex during SDS-PAGE performed by the procedure of Laemmli.²³ The similar dissociation of another complex (plasminogen activator-plasminogen activator-inhibitor complex) during SDS-PAGE performed by Laemmli's procedure has been reported.³¹

When α_2 PI-plasmin complex formation was inhibited by JTPI-1, plasmin that remained free rapidly degraded α_2 PI (Fig 6). The estimated molecular weight of the degraded α_2 PI was approximately 7 K less than that of α_2 PI, and this degraded form of α_2 PI bound to JTPI-3 but not to JTPI-2 upon immunoblotting (Fig 7). Since JTPI-2 recognizes an epitope in the C-terminal 11-K fragment (see the following paragraph), these findings suggest that free α_2 PI is very susceptible to plasmin degradation and that a susceptible bond is located in the C-terminal region of the molecule.

JTPI-2 bound α_2 PI and the α_2 PI-plasmin complex equally well (Table 1). Immunoblotting data showed that JTPI-2 bound to the C-terminal 11-K fragment (Fig 2). The fact that JTPI-2 recognizes the C-terminal 11-K fragment in α_2 PI-plasmin complexes as well as α_2 PI confirms the previous finding that the C-terminal fragment cleaved from α_2 PI upon α_2 PI-plasmin complex formation remains firmly bound to the complex and can be separated only in the presence of denaturants such as SDS.¹⁵ Although the C-terminal 11-K fragment contains the LBS binding site, the epitope recognized by JTPI-2 is separate from the LBS binding site for the following reasons: JTPI-2 did not inhibit either the binding of plasminogen to fibrin or the immediate-type antiplasmin

activity of α_2 PI at all (Figs 4 and 5), and the C-terminal 26-residue peptide that contains the LBS binding site (plasminogen-binding site) failed to inhibit binding of the antibody to α_2 PI (Fig 8). Thus the epitope for JTPI-2 seems to be located between the reactive site and the LBS binding site.

JTPI-3 bound to α_2 PI-plasmin complexes (150 K) and had no effect on the following functions of α_2 PI: antiplasmin activity (Figs 4 and 5), interference with plasminogen binding to fibrin, and cross-linking to fibrin. Although JTPI-3 did not inhibit the cross-linking of α_2 PI to fibrin, the binding of JTPI-3 to α_2 PI was inhibited by the N-terminal 12-residue peptide (Fig 8) that contains the cross-linking site.²⁹ These results suggest that the epitope for JTPI-3 is located somewhere between the cross-linking site, the glutamine in the second position from the N-terminal end, and the 12th-position lysine. When the α_2 PI-plasmin complex was incubated with plasmin, the complex gradually lost its capacity to bind JTPI-3 (Fig 3B), although any change in its molecular weight was not apparent (Fig 3A). These findings together with the suggestion that JTPI-3 recognizes the N-terminal region of α_2 PI may support the proposal that plasmin degrades the complex by cleavage of a peptide near the N-terminus of the α_2 PI component of the complex.^{15,23}

The markedly lower affinity of JTPI-1 to the α_2 PI-plasmin complex than to free α_2 PI (Table 1) provided the ability to measure free α_2 PI without significant influence from the α_2 PI-plasmin complex (Figs 9 and 10). In dilute plasma (1:400 dilution) the concentration of the α_2 PI-plasmin complex (<2.5 nmol/L) is below the range of detection for JTPI-1. Therefore an ELISA to the dilute plasma similar to that used in Fig 9 should detect only free α_2 PI.

When plasma is treated with urokinase, the plasmin that is generated immediately forms complexes with α_2 PI. At low concentrations of urokinase, α_2 PI-plasmin complex formation is proportional to the concentration of urokinase.²¹ Figure 11 demonstrates that the concentration of the α_2 PI-plasmin complex (detected by antiplasminogen) increased upon urokinase treatment, whereas the concentration of free α_2 PI (detected by JTPI-1) decreased. The total amount of α_2 PI (free α_2 PI plus the α_2 PI-plasmin complex) remained constant. Additionally, when the same plasma samples were assayed using JTPI-3 for detection (JTPI-3 detects both free α_2 PI and the α_2 PI-plasmin complex), the amount of α_2 PI detected was not influenced by urokinase treatment (Fig 11). These results indicate that under appropriate conditions the level of α_2 PI detected by JTPI-1 represents free α_2 PI.

Currently available immunologic assays for α_2 PI (such as single radial immunodiffusion, electroimmunoassay, and ELISA using polyclonal antibodies) measure not only α_2 PI but also the α_2 PI-plasmin complexes. In this respect, the present method for detection of free α_2 PI has a definite advantage because it allows an accurate determination of the α_2 PI concentration in plasma from patients such as those with disseminated intravascular coagulation or receiving thrombolytic therapy in whom the levels of the α_2 PI-plasmin complex in plasma are often markedly increased.^{5,32} The combination of an ELISA that measures free α_2 PI (detection by JTPI-1) and an ELISA that measures the α_2 PI-plasmin complex (detection by antiplasminogen) allows accurate

information to be determined about the behavior of α_2 PI in various disease states.

ACKNOWLEDGMENT

We are grateful to Dr Yoichi Sakata for his valuable advice and discussion. We are indebted to Scott Curriden at the Scripps Clinic and Research Foundation for his critical reading of the manuscript and correction of the English. We thank Ikuko Ohshima for her help in preparation of the manuscript.

Epidemiological Investigation of the Prevalence of von Willebrand's Disease

By Francesco Rodeghiero, Giancarlo Castaman, and Enrico Dini

To evaluate the prevalence of von Willebrand's disease (vWd) we carried out an epidemiological investigation among school children of the Veneto region in northern Italy. A total of 1,218 of 1,281 possible children participated in the study. They were 11 to 14 years of age, and all attended secondary schools in two distinct small areas, 70 km apart, between which there is no social contact. A blood sample was taken from each subject for determination of the blood group and von Willebrand factor (vWf) level (measured as ristocetin cofactor and expressed in IU/dL after calibration of the internal pool against an international standard), and the parents were given a questionnaire concerning hemorrhagic symptoms in the members of the family in the last three generations. Separate normal ranges were calculated for blood group O and non-O subjects (1,166 children and 289 adults) with a nonparametric method because the distribution curves of the reference values did not fit the gaussian distribution.

VON WILLEBRAND'S DISEASE (vWd) is an autosomally inherited disorder resulting from a quantitative or a qualitative defect of von Willebrand factor (vWf).¹ This protein circulates in plasma complexed to factor VIII (VIII/vWf complex) and is required for the normal adhesion of platelets to subendothelium² and for in vitro ristocetin-induced platelet aggregation.³ Clinical expressions of the disease are variable. In addition to severe cases requiring replacement therapy to stop or prevent hemorrhages, there are mildly affected patients. Furthermore, some subjects carrying the mutant gene have no hemorrhagic symptoms.^{4,5}

The mutant gene has multiple phenotypic effects consisting essentially of a prolonged bleeding time and reduced factor VIII/vWf complex-related activities (factor VIII coagulant activity, vWf antigen, ristocetin cofactor activity of vWf).⁶ The bleeding time and VIII/vWf-related activities can be easily measured by laboratory tests, but the diagnosis of this disorder may be difficult because the laboratory data may overlap with the normal range and fluctuate with time in a given patient.⁷ Recently, the identification by multimeric sizing techniques of qualitative variants of vWd has added to the complexity of the diagnosis.⁸⁻¹²

So far, the prevalence of vWd has been estimated only from the cases registered at specialized centers and indicates

Diagnoses of vWd were considered only for children who had low vWf levels and were members of a family with a convincing bleeding history (case of "probable vWd"). A final diagnosis was assigned if, in addition to these criteria, at least one other family member on the side with hemorrhagic history had a low vWf level. Of the 1,218 children examined, ten were classified as having vWd (0.82%). Taking into account the 90% confidence interval for the lower limit of the normal range, this figure could range from 7 (0.57%) to 14 (1.15%). All these subjects were mildly to moderately affected and presented features of heterozygous classic vWd (type I). Affected subjects were distributed evenly in the two areas examined. Our results suggest that the prevalence of vWd might be much higher than previously reported and that a different screening approach might be of use for patients with mild bleeding diathesis

a prevalence similar to or even lower than that of hemophilia.¹³⁻¹⁶ This paper reports the results of an epidemiological investigation of 1,218 children attending secondary school in two distinct areas of North Italy.

MATERIALS AND METHODS

Subjects. All 1,281 children aged 11 to 14 attending the three grades of secondary school in two distinct areas of the Veneto region (Province of Vicenza) were asked to participate in the investigation. The first area consists of two small neighboring towns 30 km north of Vicenza (Santorso and Piovene Rocchette, 11,676 inhabitants), and the second consists of two small neighboring towns 40 km south of Vicenza (Foiana Maggiore and Noventa Vicentina, 11,638 inhabitants). The possibility of investigating all resident children, the adequate size of the sample, and the administrative facilities caused us to choose these particular areas. Moreover, less than 10% of the two populations had a common ancestor, as judged by an analysis of family names, so that the two areas can be considered to be independent samples. Parents and physicians in charge of the children were given detailed information about the purpose and methodology of the investigation. All children for whom parents had provided written consent were admitted to the study.

Hemorrhagic symptoms were investigated through a questionnaire consisting of four sections that concerned the child under investigation, or her siblings, the father and his sibship and parents, and the mother and her sibship and parents. Specific symptoms investigated included epistaxis, hemorrhage after tooth extraction, hemorrhage after surgery, prolonged bleeding after superficial cuts, menorrhagia, postpartum hemorrhage, and easy bruising. Families for which a hemorrhagic history could be suspected were interviewed to get more detailed descriptions of reported bleeding episodes and additional information about relatives not specifically investigated in the questionnaire. Each symptom was recorded only when sufficiently fully reported and of not trivial importance. Easy bruising was considered only for male adults and menorrhagia and postpartum hemorrhage only when specific causes could be reasonably ruled out. Subjects complaining of epistaxis, whenever possible, were examined to exclude Rendu-Osler disease. A subject was recorded as definitely positive if at least two hemorrhagic symptoms were present. A family was recorded as positive if at least two members of the genetic line were positive. Laboratory investigation was offered to all available members of these families. The questionnaire

answers and interviews of family members were examined by one of us before the laboratory results were known.

Laboratory investigations. Blood was taken by venipuncture with a 19-gauge needle in the infirmary of each school between 8:30 AM and 10:00 AM after the subjects had been resting for at least 30 minutes. The samples were placed in precoded tubes and transported in refrigerated boxes to our laboratory within two hours. Repeat blood samples were taken 2 to 4 months later from all children of hemorrhagic families, and samples were also obtained from as many family members as possible.

Blood cell counts were made on EDTA-anticoagulated blood using an electronic counter (Coulter Counter IV Plus, Coulter Electronics, Hialeah, FL). ABO blood groups and Rh typing were determined using standard slide methods; secretors were identified by a saliva test. Blood for coagulation tests, collected in 3.8% sodium citrate (1:10), was centrifuged at +4 °C (15 minutes at 1,500 g) immediately after arrival at our laboratory, and platelet-poor plasma was deep-frozen and stored at -80 °C.

The ristocetin cofactor activity of vWf was measured essentially according to the method of Macfarlane et al.¹⁷ The rate of agglutination of formalin-fixed washed platelets to ristocetin (final concentration, 1.5 mg/mL) was measured by calculating the slope of the steepest part of the agglutination curve (Chrono-Log Corp aggregometer, Havertown, PA). Four dilutions of local standard plasma in buffered saline (1:1 to 1:8) were assayed in reverse order, at the beginning and at the end of each set of measurements, and the reference curve was calculated on the average of the rate of agglutination of each dilution. No significant temporal drift occurred if the assay was completed within two hours. Each sample was assayed at three different dilutions and its potency in terms of the local standard plasma calculated by fitting a straight line parallel to the reference line. When major departures from parallelism were observed, the sample was retested. Two samples, one with normal and the other with low ristocetin cofactor activity, were included in each set of measurements; the interassay variability of both samples was less than 10%. The coagulant activity of factor VIII (VIII:C) was measured using a one-stage method based on the activated partial thromboplastin time (Actin reagent, Dade, Aguada, Puerto Rico) and a dilution of the test plasma in hemophilic plasma from patients with an unmeasurable VIII:C level.¹⁸ vWf antigen was measured by the Laurell electroimmunoassay technique using a polyclonal antiserum anti-vWf antigen from Behringwerke (Marburg, West Germany).¹⁹ The ratios of the potency of the samples to the local standard plasma were calculated as in the ristocetin cofactor assay.

The local standard plasma, plasma from 98 healthy hospital staff members, was collected on a single morning and pooled. The same local standard, stored at -80 °C, was used throughout the study. It was calibrated for factor VIII:C, vWf:Ag, and ristocetin cofactor activity against the First International Reference Preparation for Factor VIII Related Activities in Plasma (IRP) (kindly supplied by Dr T.W. Barrowcliffe, National Institute for Biological Standards and Control, London). Calibrations, three at the beginning and three at the end of the study, were made as suggested by Kirkwood and Snape.²⁰ The local plasma standard and the lyophilized IRP were diluted in plasma severely deficient in vWf for the purpose of calibrating ristocetin cofactor activity. The potency estimations were combined by taking a weighted geometric mean, the weights being inversely proportional to the variances of the log potency estimates. The ristocetin cofactor activity of vWf in plasma is simply referred to as "vWf" in the text. The multimeric composition of factor VIII/vWf was analyzed in the laboratory of Professor Mannucci (Milan, Italy), as previously published.²¹

Definition of the normal range of vWf. Values of vWf obtained from children without a family history of hemorrhage were used for

the definition of the normal range of vWf. An analysis of the variance and the Newman-Keuls test²² showed significantly lower level of vWf in blood group O subjects. Separate normal ranges were calculated for O and non-O subjects. The values were not normally distributed and showed significant positive kurtosis and skewness. Several transformations including log, square root, and inverse hyperbolic sine did not correct all kurtosis and skewness, and the Kolmogorov-Smirnov test²³ showed significant deviation from normality. Normal ranges were defined by calculating 2.5 and 97.5 percentiles by a nonparametric method.²⁴ A 90% confidence interval for each end point thus obtained was calculated on the basis of a binomial probability distribution.²⁴ All reference values were included because no outliers were found. The normal range of vWf in adults was defined in 289 subjects of both sexes aged 19 to 65 without a personal or family history of hemorrhage and who were not taking contraceptive drugs. One hundred twenty-four of them were regular blood donors, 98 were healthy hospital staff members, and 67 were teachers or employees of the schools.

Criteria for the diagnosis of vWd. The diagnosis was considered only for subjects belonging to a family recorded as positive for bleeding history. Subjects satisfying this criterion and also having vWf levels below the normal range were classified as cases with "probable vWd." A definite diagnosis of vWd was considered when at least one other member, on the hemorrhagic side of the subject's family, had a low vWf level.

RESULTS

The potency ratios of the local standard relative to the international standard measured at the beginning and at the end of the study 18 months later showed similar potencies. Potency estimations were combined and assigned to the local standard plasma (Table 1).

A total of 1,218 children participated in all stages of the research, with similar rates of participation in the areas north (594/620) and south (624/661) of Vicenza; the male-to-female ratio was 1.01. Among the questionnaires, 202 were selected because one or more of the reported episodes could be regarded as hemorrhagic. Parents of children of these families were interviewed. In this way, 49 families (21 north and 28 south of Vicenza) could be classified as positive (107 members with two or more hemorrhagic symptoms). Epistaxis accounted for 39% of the 268 identified symptoms, followed by bleeding after tooth extraction (20%), menorrhagia (18%), postpartum hemorrhage (8%), prolonged bleeding after superficial cuts (4%), after tonsillectomy or adenoidectomy (4.5%), after surgery (3.5%), easy bruising (2%), and other manifestations (1%). Values of vWf in the

Student's *t* test did not show statistically significant differences between potency ratio values found at the beginning and at the end of the study for each activity.

Abbreviation: CL, confidence limits.

children of these families (52 subjects, 24 male and 28 female) were treated separately and normal ranges calculated from the remaining 1,166 children.

Subjects of group O had a significantly lower mean vWf value than subjects of group A, B, or AB ($P < .001$; Newman-Keuls multicomparison test) (Table 2). The age distribution of vWf levels was independent of sex, Rh phenotype, secretory status, or area of residence. In 289 adults, vWf was also similarly lower in group O subjects, whereas no significant differences were observed in relation to sex or Rh phenotype. Only in subjects of group O was there a significant correlation with age ($r = .33$; $P < .001$). Table 2 shows the mean values and normal ranges of vWf for children and adults of O and non-O groups. A correction for age in group O adults was not done.

Figure 1 shows the distribution of vWf levels in the 52 children belonging to families with hemorrhagic histories.

Six subjects of group O and four of group non-O fell below the 2.5 percentile. Fourteen children had vWf levels below the upper limit of the 90% confidence limits (nine of group O, five of group non-O), and seven were below the lower limit (three of group O, four of group non-O). Subjects of group O in the normal range seem to be clustered near its lower end.

Table 3 lists the laboratory findings and hemorrhagic symptoms in the 14 children with low vWf levels and their symptomatic family members.

Six children (four to nine according to the 90% confidence interval of the 2.5 percentile) could be definitely classified as having vWd because other family members had vWf levels below the normal range, whereas for another four (three to five) the diagnosis of vWd was "probable." Similar prevalence of the disease was found in the two areas. vWd was more frequent in females (eight of 14) and in O group children (nine of 14), (P values, .091 and .105, not significant). vWf was below the normal range in nine of 24 relatives in whom it was measured (38%).

The strict correlation between vWf and vWf:Ag and between vWf and VIII:C (in both cases $r = .83$, $P < .001$) suggests that these subjects may have type I vWd. This was confirmed by multimeric analysis of all affected children. vWf levels in these subjects are distributed around half of the normal value, as would be expected in heterozygotes of an autosomal dominant trait. A clear hemorrhagic story could be traced in all families, and symptoms, present in all the children, appeared to be transmitted in an autosomal dominant fashion.

Table 2. Distribution of the vWf Level in Normal Subjects

Subjects	No.	Blood Group	vWf Level (IU/dL)		
			Mean (Range)	2.5 Percentile (90% CI)	97.5 Percentile (90% CI)
Children	510	O	99.7 (37.4-177.6)	61.0 (55.6-66.3)	149.8 (145.5-154.1)
	656	Non-O	115.8 (43.9-230.0)	77.0 (76.0-81.3)	164.0 (156.2-175.5)
Adults	121	O	88.7 (46.0-123.1)	51.8 (46.0-54.9)	118.8 (116.6-123.1)
	168	Non-O	110.6 (69.5-203.0)	75.1 (69.5-81.3)	167.6 (144.5-203.0)

Abbreviation: CI, confidence interval.

Fig 1. Distribution of vWf levels in the 52 children belonging to hemorrhagic families. Normal ranges (—) and 90% confidence intervals (---) around the lower and upper end points are indicated.

Repeat blood samples were obtained from 44 of the 52 children of hemorrhagic families 2 to 4 months after the first investigation. The mean values of vWf were the same as before (87.9 v 88.2), with a mean difference between first value and second values for each subject of 11.8 ± 9.5 . The vWf values of the second samples confirmed the diagnoses for 12 of the 14 children, and four additional cases of vWd were detected.

DISCUSSION

The criteria for the diagnosis of vWd used in this investigation were conservative and aimed at reducing to a minimum the rate of inclusion of false-positive subjects. Subjects belonging to hemorrhagic families that had vWf below the normal range were recorded as cases of "probable vWd." Definite diagnoses were made only when, in addition, at least one other member with low vWf could be found among relatives on the hemorrhagic side of the family.

Diagnostic criteria (laboratory and clinical). The lower normal limit of the vWf level was chosen as the value below which lie 2.5% of normal subjects and was defined on the basis of the values found in more than 1,000 normal subjects. Because the vWf distribution showed a positive kurtosis and skewness that was not completely removed by several transformations, we used a nonparametric method for the definition of the 2.5 and 97.5 percentiles and the 90% confidence intervals around these limits. Nonparametric methods make no assumption about the type of distribution of the reference values and are thus more precise and recommended in situations that differ from the ideal model of normality.²⁴⁻²⁶ Homogeneity between the reference and investigated groups was assured because both were drawn from the same population of children. Moreover, because vWf was found to be lower in group O subjects, separate normal ranges were calculated for O and non-O subjects. Uniformity of measurement of vWf during the study was guaranteed by using a single reference standard that showed no loss of potency relative to the international standard (Table 1) and by performing the vWf assay shortly after sample collection. No changes in vWf levels were found in relation to the time of blood sampling.

*Below the lower limit of the 90% confidence interval of 2.5 percentile.

†Below the 2.5 percentile.

‡a, epistaxis; b, bleeding after tooth extraction; c, menorrhagia; d, bleeding after surgical procedures; e, postpartum hemorrhage; f, prolonged bleeding after superficial cuts; g, easy bruising (considered for the purpose of defining hemorrhagic diathesis only in male adults).

Conservative criteria were used for the definition of hemorrhagic diathesis, and two or more positive members were required to consider a family as positive. The frequency of "bleeders" in the general population is unknown, but using criteria less strict than the ones adopted in this study, Miller et al²⁷ were able to classify as symptomatic as many as 23% of normal subjects, a figure that would undermine the discriminant power of this parameter. In contrast to their data, only 26 children (2%) and only 107 relatives among the approximate 14,000 for whom we had direct or indirect information through questionnaires and interviews were classified as positive. In this way, a total of 52 subjects (from 49 families) out of 1,218 investigated were recorded as belonging to hemorrhagic families.

The a priori probability of a child being a member of a hemorrhagic family is thus .042 (52/1218), which, when multiplied by .025 (the probability of false-positive classification on the basis of vWf measurement), yields a probability of about .001 of a "normal child" being falsely classified as a case of "probable vWd." The probability of misclassification is, of course, greatly reduced in the presence of other relatives with low vWf levels, and in this case it seems appropriate to consider the diagnoses as definite.

Epidemiology of vWd. Among the 1,218 children investigated, ten were classified as affected (four cases as "probable vWd," six cases as definitely proven). More precisely, taking into consideration the 90% confidence interval of the lower end point of the normal range (in fact, all the values in

this interval have identical significance), there would be from seven (three "probable cases," four definite cases) to 14 (five "probable cases," nine definite cases). The calculated prevalence of vWd in our population is thus estimated to be between 0.57% and 1.15% (Table 3). All these subjects appear to be heterozygous and to have inherited the disorder in an autosomal dominant fashion. The phenotypic and laboratory characteristics and multimeric composition were those of classic vWd (type I).

A theoretical prevalence of 25 of 1,000,000 homozygotes is anticipated according to the Hardy-Weinberg equation on the basis of 1% heterozygotes in the population, but a possible genotypic heterogeneity of classic vWd, unrecognized by our methodology, would make the Hardy-Weinberg equation²⁸ inapplicable. Nevertheless, homozygous patients for the classic type I dominant vWd are likely to be more frequent than homozygotes for type III recessive vWd, who are estimated to be between 0.11 and 0.55 out of 1,000,000 in Europe²⁹ and 3.1 and 3.2 out of 1,000,000 in Sweden and Israel.^{14,29,30} Thus, in diagnosing type III vWd, one has to be very careful that the proband is not the offspring of two nonmanifesting type I patients because rare instances are known in which severely affected cases were born of asymptomatic type I vWd parents.^{27,31}

Although repeated measurements of vWf in patients with vWd may yield variable results,⁷ the classification of cases in this investigation showed little dependence on repeating the vWf assay. In fact, 12 of the 14 subjects had their diagnoses confirmed by the second value. Moreover, four additional children would have been detected by considering the lowest value found in the two determinations.

An assay for vWf (ristocetin cofactor activity) was found to be the single most useful test for identification of transmitters and symptomatic members in kindreds with the disease.^{32,33} In this study a vWf assay was preferred to other tests such as a vWf antigen (vWf:Ag) on the basis of this consideration and because variant forms of vWd are known in which vWf:Ag is normal or near normal. Nevertheless, Miller et al³² could identify only 42% of the transmitters by the vWf assay in two large kindreds with classic vWd. In several large kindreds with classic vWd by using separate normal ranges for O and non-O subjects, we were able to identify about 50% of the transmitters (data not published), and in reasonable accord with these figures, in this study we were able to identify as transmitters about 40% of the hemorrhagic relatives in families of children with low vWf.

Considering the limitations of the vWf assay for diagnosis and the conservative criteria for the definition of hemorrhagic diathesis, probably 50% or more of vWd cases could go unrecognized with a methodology like the one used in this study (false-negative subjects). Nevertheless, the prevalence of vWd found in this investigation is much higher than the prevalence previously estimated from cases registered at

specialized centers, which appeared to be similar to or even lower¹³⁻¹⁶ than that of hemophilia.³⁴ This method of calculating the prevalence of a disease with highly variable clinical expression is unreliable. Moreover, the significantly lower level of ristocetin cofactor activity (this study) and vWf antigen in subjects of group O^{35,36} leads to an overestimation of vWd in O subjects and to an underestimation in non-O subjects unless strictly defined normal ranges are used.

Although the two geographic areas investigated here can be regarded as independent samples, almost identical prevalences of vWd were found. Hence, because these areas do not present particular features, we think that the prevalence of vWd estimated in this study can apply to the Caucasian population in general. However, in extrapolating the prevalence found in children aged 11 to 14 to subjects of all ages we must consider a possible bias in the upward direction. In fact, children from larger families have a greater probability of being included, and thus there is a potential "founder effect." Actually, only one family among those who contributed with positive cases had additional children (either positive or negative) included in the study. Thus, although subjects 4 and 7 in Table 3, who are siblings, should be considered as a single case, this does not substantially change our prevalence estimation.

Practical implications. Assuming a 2% prevalence of subjects carrying the mutant gene for vWd in the population and a 50% sensitivity of the vWf assay in identifying these carriers, the vWf assay would have a predictive value of 29% for positive results (true positives/total positives) and 98.9% for negative results (true negatives/total negatives). The efficiency of the test (percentage of true-positive and true-negative results) would be 96.5%. Furthermore, limiting its use for subjects with evidence of personal or family histories of hemorrhage would virtually abolish the misclassification of normal subjects (about one in 1,000 false-positives in this study). It has to be emphasized that, to obtain these results, normal ranges have to be defined separately for O and non-O subjects.

Considering the frequency of vWd suggested by this study, we think that a vWf assay (ristocetin cofactor activity) should be included among the first level screening tests for evaluation of subjects with mild bleeding diathesis even in presence of normal routine screening tests.

ACKNOWLEDGMENT

We are most grateful to Professor P.M. Mannucci for helpful and valuable criticism throughout the study. This work could not have been carried out without the enthusiastic collaboration of the children and their families. We are also indebted to the physicians in charge of the children and to the school directors. The excellent technical assistance of E. Padoan and B. Vachel, the expert execution of blood sampling by E. Turetta, and the secretarial work of F. Cernecca are greatly appreciated.

Fibrinolysis in Pregnancy: A Study of Plasminogen Activator Inhibitors

By Egbert K.O. Kruithof, Chiên Tran-Thang, Annelise Gudinchet, Jacques Hauert, Grazia Nicoloso, Claire Genton, Hansjörg Welti, and Fedor Bachmann

During pregnancy the plasma concentration of two different inhibitors of plasminogen activators (PAIs) increases. The only one found in the plasma of nonpregnant women (PAI1) is immunologically related to a PAI of endothelial cells; its plasma activity, as deduced from the inhibition of single-chain tissue-type plasminogen activator (t-PA), increased from 3.4 ± 2.3 U/mL (mean $\pm$ 95% confidence limits) in the plasma of nonpregnant women to 29 ± 7 U/mL at term, and its antigen level, measured by a radioimmunoassay, increased from 54 ± 17 ng/mL to 144 ± 25 ng/mL. In pregnancy plasma a second PAI (PAI 2) related to a PAI found in placenta extracts was observed. Its level, quantified with a radioimmunoassay, increased from below the detection limit (~ 10 ng/mL) in normal plasma to 260 ng/mL at term. One hour after delivery, PAI 1 activities and antigen decreased sharply, but the PAI 2 antigen levels remained constant. Three days later, the PAI 1 antigen levels had fallen to normal levels, but the PAI 2

antigen levels were still at least eightfold above the nonpregnant values. During pregnancy, the t-PA and pro-urokinase (u-PA) antigen concentrations increased 50% and 200%, respectively, whereas the plasminogen and α_2 -antiplasmin levels remained constant. Despite the large variations in the levels of PAs and PAIs, the overall fibrinolytic activity as measured in diluted plasma by a radioiodinated fibrin plate assay did not change significantly. Just after delivery, a great increase in the t-PA antigen levels was observed. Three to five days after delivery most parameters of the fibrinolytic system were normal again. Our results demonstrate that during pregnancy and in the puerperium profound alterations of the fibrinolytic system occur that are characterized by increases in PAs and their inhibitors, but these alterations do not affect the overall fibrinolytic activity.

© 1987 by Grune & Stratton, Inc.

DURING PREGNANCY profound changes in the hemostatic system are observed. Plasma levels of fibrinogen, factor VII, factor VIII and von Willebrand's factor increase.¹⁻⁴ The prevailing opinion states that the fibrinolytic activity of plasma, as measured in euglobulin precipitates, decreases during pregnancy.⁴⁻¹² Some authors, however, observed an increased fibrinolytic activity of unfractionated whole blood¹³ and a higher level of fibrin degradation products.¹⁴ The decreased fibrinolytic activity of euglobulins is generally attributed to an increased plasma level of a plasminogen activator inhibitor (PAI), possibly derived from the placenta.^{10-12, 15-17} These studies, however, did not take into account the existence of at least two different PAIs, one purified from endothelial cells (PAI 1)¹⁸ and one purified from placenta,¹⁹ leukocytes,²⁰ and histiocytic lymphoma cells (PAI 2).²¹ In a recent study, Nilsson et al showed that both PAIs are present in pregnancy plasma.²² No study exists yet that separately measures the levels of the two PAIs. With the development of more specific methods to determine the two PAIs, tissue-type plasminogen activator (t-PA), and urokinase (u-PA) in human plasma it is now possible to analyze in more detail the modifications of the

fibrinolytic system during pregnancy. In the present study we therefore measured in nonpregnant women, during pregnancy and after delivery, the plasma antigen levels of PAI 1, PAI 2, t-PA, u-PA, plasminogen and α_2 -antiplasmin, and also the PA and PAI 1 activity. Our results show that during pregnancy the levels of the two PAIs, t-PA, and u-PA strongly increase but that the overall fibrinolytic activity remains relatively constant.

MATERIALS AND METHODS

Materials. Thrombin (Topostasin) was obtained from Hoffmann-La Roche, Basel, Switzerland; fibrinogen (bovine, plasminogen rich) from Poviet, Oss, The Netherlands; ¹²⁵I-fibrinogen (FIBI-125C, 1 mCi/mg) from Sorin, Saluggia, Italy; aprotinin (Trasylol) from Bayer, Leverkusen, Federal Republic of Germany; lodogen from Pierce, Oud Beijerland, The Netherlands; Na¹²⁵I from New England Nuclear, Dreieich, Federal Republic of Germany; all reagents for sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) from Bio-Rad, Richmond, CA; and Sephadex G-100, Concanavalin A (ConA) Sepharose, CNBr-activated Sepharose, lysine-Sepharose, and protein A-Sepharose from Pharmacia Fine Chemicals, Uppsala, Sweden. The World Health Organization International Reference Preparations of human u-PA (NIBSC 66/46) and human t-PA (NIBSC 83/517) were provided by Dr P.J. Gaffney from the National Institute for Biological Standards and Control, London.

Plasminogen activators. Human t-PA was purified as previously described. It consisted mainly of single-chain (sc) t-PA.²³ u-PA (two-chain [tc], 54 kDa) was a gift of Dr Sauser of Sero Laboratories, Coinsins, Switzerland. Antisera against t-PA and u-PA were raised in rabbits. IgG was isolated by affinity chromatography on protein A-Sepharose. u-PA was radioiodinated with carrier-free ¹²⁵I by using lodogen according to the procedure of Fraker and Speck,²⁴ as described before.²⁵ In general, 20% to 40% of added ¹²⁵I was incorporated into protein under the labeling conditions used. The radioiodinated u-PA had a specific radioactivity of 10 to 40 nCi/ng (between 10 and 40 atoms of ¹²⁵I incorporated per 100 molecules of u-PA). The activity of the t-PA and u-PA preparations used in this study were calibrated against their respective international reference preparations in a fibrin plate assay.

Plasminogen activator inhibitors. PAI 1 was purified from the

conditioned medium of hydrocortisone (10^{-7} mol/L) stimulated cells of the human fibrosarcoma cell line HT 1080²⁶ by affinity chromatography on ConA-Sepharose,¹⁸ ion-exchange chromatography on diethylaminoethyl Sephacel, and gel filtration on Sephadex G-100. The final product showed one band on reduced and nonreduced SDS-PAGE and was immunoprecipitable by antibodies prepared against a PAI purified from the conditioned medium of bovine¹⁸ and human²⁷ endothelial cells (gifts from Drs Loskutoff, La Jolla, CA, and Sprengers, Leiden, The Netherlands) respectively.

PAI 2 was purified from the conditioned medium of phorbol myristate acetate (30 ng/mL)-stimulated cells of the human histiocytic lymphoma cell line U-937, and anti-PAI 2 antibodies were raised in rabbits as previously described.²¹ PAI 1 did not react with antibodies to PAI 2 and vice versa. PAI 2 was found to be indistinguishable from a PAI partially purified from human placenta by the following criteria: (1) a line of complete identity was obtained in double immunodiffusion, (2) identical molecular weights were obtained after SDS-PAGE followed by electroblotting and immunologic detection using immunopurified anti-PAI 2 IgG and peroxidase-conjugated goat-IgG antirabbit IgG, and (3) the second-order rate constant of the reaction of placental PAI and PAI 2 with u-PA and t-PA were similar.²¹ PAI 1 and PAI 2 were radioiodinated using the method of Fraker and Speck.²⁴ Radioiodinated inhibitor was separated from free ¹²⁵I by passage over a 12-mL column of Sephadex G-25. The specific radioactivity of the radiolabeled PAI preparations was between 15 and 50 nCi/ng (corresponding to 15 to 50 molecules of ¹²⁵I incorporated per 100 molecules of PAI 1 or PAI 2).

Plasmas. Blood was obtained by venipuncture, anticoagulated with buffered citrate (nine parts of blood were mixed with one part of 0.1 mol/L sodium citrate/citric acid, pH 4.5), and centrifuged for 15 minutes at 3,600 g at 4 °C. The plasmas were stored at -70 °C. A normal plasma pool was made from the blood of 50 healthy blood donors.

Subjects. The subjects studied were (1) 90 pregnant women whose pregnancy proceeded normally. For each 4-week period of pregnancy, except the first, ten women were admitted. The last period comprised the 37th week until term. Also studied were (2) ten women postpartum (mean time since delivery, 77 ± 54 minutes [mean $\pm$ SD]), (3) ten women three to five days after delivery, and (4) ten apparently healthy, nonpregnant women of the same age group (27 ± 4 years) as the pregnant women (27 ± 5 years).

Immunoradiometric assay for t-PA in plasma. The t-PA antigen levels in human plasma were determined by using an immunoradiometric assay essentially as described by Rijken et al.²⁸ Standard curves were made using a t-PA preparation standardized against the International References Preparation of t-PA. This preparation has a specific activity of 500,000 IU/mg protein (1 IU = 2 ng).

Radioimmunoassay for (pro) u-PA in plasma. One hundred microliters of plasma diluted five times with immunodilution buffer (50 mmol/L Tris-HCl, pH 7.4, 200 mmol/L NaCl, 10 mmol/L EDTA, 0.1% bovine serum albumin, and 0.05% Na₂S₂O₃) was mixed with 100 μ L anti-u-PA IgG that had been diluted such (1:100,000) that in the absence of added cold u-PA half of the ¹²⁵I-labeled u-PA bound to the antibodies. The sample was incubated four hours at room temperature with IgG. Thereafter, 50 μ L of ¹²⁵I-u-PA (containing 2,000 cpm radiolabel) was added and incubated overnight at 4 °C. The following day, 100 μ L of a cellulose suspension to which donkey antibodies to rabbit IgG had been coupled (Sac-Cel, Wellcome Reagents, Beckenham, UK) was added. The suspension was incubated 30 minutes at room temperature, diluted by the addition of 2 mL of 0.15 mol/L NaCl, and centrifuged for five minutes at 200 g. The pellet was twice washed with 2 mL of 0.15 mol/L NaCl and counted in a gamma counter. The radioactivities after deduction of

the nonspecific binding of ¹²⁵I-u-PA to Sac-Cel in the absence of added IgG were compared in a logit-log plot with a standard curve of u-PA that had been calibrated against the international reference preparation of u-PA (specific activity, 100,000 U/mg).

Radioimmunoassay for PAI 1 and PAI 2 in plasma. The methodology used for the determination of PAI 1 and PAI 2 antigen was identical to that described for u-PA. Rabbit antbovine PAI 1 antiserum (a gift from Dr Loskutoff, La Jolla, CA) was used in a dilution of 1:1,000, and immunopurified rabbit anti-PAI 2 IgG was used in the concentration of 60 ng/mL. The antigen levels were measured by comparison in a logit-log plot with standard curves of pure PAI 1 or PAI 2. The protein concentrations of the PAI 1 or PAI 2 stock solutions were determined using the protein assay of Bradford²⁹ and bovine serum albumin as the standard.

Assay for plasminogen and α_2 -antiplasmin. The plasminogen and α_2 -antiplasmin levels were determined by rocket immunoelectrophoresis using commercially available antisera (Behringwerke, Marburg an der Lahn, Federal Republic of Germany). Rocket heights were compared with those of various dilutions of a normal human plasma pool and the results expressed in percent with respect to the plasma pool.

Assay for the total PA activity in plasma. The PA activity was measured using a ¹²⁵I-fibrin plate method.^{30,31} Plasminogen-free bovine fibrinogen was converted to fibrin monomers and further purified by three steps of polymerization and dissolution in acetic acid as described by Haverkate and Timan.³² Human ¹²⁵I-fibrinogen of clinical grade was rendered plasminogen free by affinity adsorption to lysine-Sepharose.³³ The ¹²⁵I-fibrin plate was prepared using these two fibrinogen solutions exactly as described by Sharoni et al.³¹ No thrombin was detectable in these plates with a chromogenic substrate assay (detection limit of 5 pg/mL). Prior to use, the wells were incubated for 15 minutes with sterile phosphate-buffered saline. The buffer was replaced with a mixture of 250 μ L of a solution of plasminogen (5 μ g/mL) and 100 μ L of a 50- or 100-fold dilution of plasma in 0.1 mol/L Tris-HCl, pH 7.5, containing 1% bovine serum albumin. The plates were incubated at 37 °C; after three and six hours, 50- μ L aliquots were removed to determine the degree of ¹²⁵I-fibrinolysis. The percentage of ¹²⁵I-fibrinolysis was compared with that of standard curves using a laboratory reference preparation of human t-PA that had been calibrated against the international t-PA reference preparation.

PAI 1 activity assay. Because the reaction rate between PAI 2 and sc t-PA is quite slow^{21,34} but fast between PAI 1 and sc t-PA,²⁵ we have adapted the previously described assay for PAI activity in plasma,²⁵ taking care to add to the plasma a t-PA preparation (final concentration, 42.5 U/mL) that contained less than 10% of the tc form.

Preparation of immobilized antibodies. IgG was prepared by affinity chromatography on protein A-Sepharose from 0.5 mL of rabbit preimmune serum, antiserum directed against PAI 1,¹⁸ and antiserum directed against PAI 2.²¹ The IgG was dialyzed overnight against two changes of 0.1 mol/L sodium bicarbonate, pH 8.1, and coupled to 1 mL of CNBr-activated Sepharose 4B.

Immunologic comparison of PAIs in normal and pregnancy plasma. Radioiodinated u-PA (10 μ L, 200 ng/mL, 4×10^6 cpm/mL) was incubated for ten minutes at 37 °C with 200 μ L of human plasma. Forty microliters of the mixture was added to 200 μ L of a 25% suspension of immobilized preimmune IgG, anti-PAI 1 or anti-PAI 2 IgG in 50 mmol/L imidazole and 140 mmol/L NaCl, pH 7.35. After a further 20 minutes' incubation at 25 °C, the gel was spun down (five minutes, 1,000 g) and the supernatant diluted twofold with SDS sample buffer. SDS-PAGE in a 7.5% gel³⁵ of a 50- μ L sample and autoradiography was performed as described previously.²⁵

RESULTS

PAI 1 and PAI 2 levels in pregnancy plasma. The PAI 1 activity in the plasma of nonpregnant women was extremely variable (3.4 ± 2.3 U/mL, mean $\pm$ 95% confidence limits of the error of the mean). In the first 3 months of pregnancy, the PAI 1 activity was slightly, but nonsignificantly higher. Thereafter an almost linear increase in the PAI 1 activity to 29 ± 7 U/mL at term was observed (Fig 1). One hour after delivery, the PAI 1 activity decreased approximately 50% to 15 ± 9 U/mL, and the levels were normal three to five days after delivery.

As observed for the PAI 1 activity, the PAI 1 antigen levels in nonpregnant women were quite variable (55 ± 17 ng/mL). During the first 2 months of pregnancy, the PAI 1 antigen levels appeared to decrease slightly; thereafter they increased steadily to a maximum of 147 ± 32 ng/mL, attained between 32 and 36 weeks of pregnancy (Fig 2). After delivery the PAI 1 antigen levels decreased sharply within one hour and were normal three to five days later.

The PAI 2 antigen levels in nonpregnant women were below the detection limit (<10 ng/mL). From 4 to 8 weeks of pregnancy the PAI 2 was measurable in about half of the subjects. After that it was detectable in all plasmas, and an almost linear increase of PAI 2 antigen concentration was observed until the 32nd week of pregnancy when the mean levels stabilized at around 240 ng/mL (Fig 3). In contrast to the PAI 1 activity and antigen, the PAI 2 antigen did not decrease within one hour postpartum. Three to five days after delivery the mean level of 77 ± 27 ng/mL of PAI 2 was still at least eightfold higher than in nonpregnant women.

Complex formation of u-PA with PAI 1 and PAI 2 in normal and pregnancy plasma. To verify whether PAIs

Fig 1. PAI 1 activity in plasma during pregnancy and postdelivery. The PAI 1 activity in plasma was estimated from the inhibition of sc t-PA, as indicated in Materials and Methods. Plasmas were obtained from ten nonpregnant (N) and 90 pregnant women. Each 4-week period is represented by ten women. Plasmas were also obtained from ten women one hour postpartum and ten women three to five days after delivery. The results are expressed as the means $\pm$ 95% confidence limits of the error of the mean.

Fig 2. Plasma antigen levels of PAI 1 during pregnancy and postdelivery. The PAI 1 antigen levels were measured by a radioimmunoassay in the plasma of the 120 women indicated in the legends to Fig 1.

other than PAI 1 and PAI 2 are present in normal and in pregnancy plasma, ^{125} I-u-PA was added to a plasma pool obtained from nonpregnant women or from women in the last trimester of pregnancy and the immunologic identity of the complexes formed established. For this experiment u-PA was chosen rather than t-PA because u-PA reacts rapidly with both PAIs and sc t-PA only with PAI 1. The incubation of ^{125} I-u-PA in normal plasma resulted mainly in the formation of a 95 kDa complex (Fig 4). This complex bound to immobilized anti-PAI 1 IgG but not to anti-PAI 2 IgG. In pregnancy plasma, three complexes in the molecular weight region of 85,000 to 110,000 were formed. The largest and the smallest ones were retained by immobilized anti-PAI 2 IgG and the middle one by anti-PAI 1 IgG. These results,

Fig 3. Plasma antigen levels of PAI 2 during pregnancy and postdelivery. The PAI 2 antigen levels were measured by a radioimmunoassay in the plasma of the 120 women indicated in the legends to Fig 1.

Fig 4. Immunologic identity of inhibitors of u-PA in normal plasma and late pregnancy plasma. (A) ^{125} I-u-PA alone. (B and C) ^{125} I-u-PA incubated at a final concentration of 20 ng/mL for ten minutes in a plasma pool of nonpregnant (B) or late pregnancy women (C). Thereafter the plasmas were passed either over a column of immobilized anti-PAI 2 IgG (lane 1), anti-PAI 1 IgG (lane 2) or preimmune IgG (lane 3). The complexes not bound to the columns were analyzed by SDS-PAGE in a 7.5% gel followed by autoradiography.

therefore, provide evidence that in pregnancy plasma PAI 1 exists in one form, whereas two different forms of PAI 2 might exist.

PA activity in plasma during pregnancy. Figure 5 shows that the PA activity in nonfractionated diluted plasma as measured on radioactive fibrin plates remained essentially constant during pregnancy and shortly after delivery. The slight changes observed were not significant. However, three to five days after delivery the PA activity levels were significantly lower than during the last period of pregnancy ($P < .001$, Mann-Whitney test) or in nonpregnant control women ($P < .005$).

Antigen levels of t-PA, (pro)-u-PA, plasminogen and α_2 -antiplasmin in pregnancy plasma. The surprising observation of an unchanged fibrinolytic activity in the presence of strongly increased levels of two different PAIs prompted us to study also the t-PA, (pro)-u-PA, plasminogen, and α_2 -antiplasmin antigen levels. During pregnancy the t-PA antigen increased from 2.2 ± 0.8 ng/mL (mean $\pm$ 95% confidence limits) in nonpregnant women to a plateau value between 3.0 and 3.6 ng/mL in the last two trimesters of

Fig 5. Plasma PA activity during pregnancy and postdelivery. The PA activity was measured on a radioactive fibrin plate using diluted nonfractionated plasmas of the 120 women as indicated in the legend to Fig 1.

pregnancy (Fig 6). One hour after delivery a doubling of the t-PA levels (6.5 ± 1.1 ng/mL) with respect to late pregnancy values was observed. Three to five days after delivery they were slightly, but significantly higher than those in nonpregnant women. The behavior of (pro)-u-PA antigen during pregnancy was quite different. An almost linear increase from 19 ± 3 ng/mL in nonpregnant women to a plateau level of 46 ± 3 ng/mL at 32 weeks of pregnancy was observed (Fig 7). Thereafter the mean (pro)-u-PA levels remained near this value until delivery. Just after delivery the u-PA levels increased slightly, but significantly ($P < .05$) to 52 ± 4 ng/mL. Three to five days postpartum the mean u-PA level was still greatly increased with respect to that in nonpregnant women (35 ± 3 v 19 ± 3 ng/mL; $P < .01$).

Fig 6. t-PA antigen levels during pregnancy and postdelivery. The t-PA antigen levels were measured by an immunoradiometric assay in the plasma of the 120 women as indicated in the legend to Fig 1.

Fig 7. (Pro)-u-PA antigen levels during pregnancy and postdelivery. The u-PA antigen levels were measured by a radioimmunoassay in the plasma of the 120 women as indicated in the legend to Fig 1.

A slight but not significant increase in the plasminogen and α_2 -antiplasmin levels was observed during pregnancy and in the puerperium.

DISCUSSION

It has been known for many years that during pregnancy profound modifications of the coagulation and the fibrinolytic system occur.¹⁻¹⁷ Our study, however, is the first to measure systematically and quantitatively the behavior of several newly described fibrinolytic components of human plasma, particularly of two different inhibitors of t-PA and of u-PA. PAI 1 is synthesized by the endothelial cells and is present in plasma and in blood platelets.^{18,25,27,36-38} PAI 1 exists in an active and a latent form.^{39,40} The active form of PAI 1 readily inhibits tc u-PA³⁶ and tc t-PA and also sc t-PA²⁵ but is rather labile and at room temperature is transformed to a latent (inactive) form with a half-life of approximately two hours.⁴⁰ Antibodies directed against PAI 1 do not cross-react with PAI 2 produced by histiocytic lymphoma cells and vice versa.^{21,22} PAI 2 also has been extracted and purified from human placenta and is therefore often termed placental PAI.^{15,19} It is a very efficient inhibitor of tc u-PA and tc t-PA but inhibits sc t-PA poorly.^{25,34}

We observed striking increases in the level of PAI 1 and PAI 2 as well as moderate increases in the t-PA and u-PA antigen levels. Our quantitative measurements confirm the recent qualitative observations of Nilsson et al who found that pregnancy plasma contains two different PAIs²² and those of Lecander and Åstedt⁴¹ who reported increased antigen levels of a placenta-derived PAI with characteristics similar to that of PAI 2. The PAI 1 levels increased steadily after the 20th week of pregnancy and, at term, were threefold higher than in nonpregnant women. The PAI 2 levels were below the detection limit in normal plasma and, at term,

were more than 25-fold increased. The PAI 1 activity levels in plasma, as determined from the inhibition of sc t-PA, correlated better with PAI 1 than with PAI 2 antigen concentration. This was particularly noteworthy just after delivery when the PAI activity and PAI 1 antigen levels decreased sharply and PAI 2 remained high. We may therefore conclude that the PAI 1 activity assay is relatively insensitive to PAI 2. We observed, however, a quantitative discrepancy between the PAI 1 activity and PAI 1 antigen levels. In the last trimester, the PAI activity was on average 28 U/mL, corresponding to 60 ng of PAI per milliliter of plasma, whereas the PAI 1 antigen levels were approximately twofold higher. Two possible explanations for this discrepancy exist. In normal plasma virtually all t-PA is bound to PAI 1⁴²; consequently, about 3 to 4 ng/mL of PAI are bound to t-PA and not measured by our activity assay. However, because the observed discrepancy is one order of magnitude greater, it can only partially be explained by the inactivation of PAI 1 by t-PA. We must therefore assume that part of the plasmatic PAI 1 is present in the latent, inactive form.^{27,39,40}

When added to pregnancy plasma, tc u-PA formed two different complexes with PAI 2 of approximately 95 and 115 kDa. The two forms of PAI 2 probably correspond to a heavier glycosylated and a lighter nonglycosylated form of PAI 2⁴³ or may be due to cleavage of the PAI 2 molecule after its interaction with u-PA.²¹

Within one hour after delivery, the concentration of some components of the fibrinolytic system changed dramatically: the doubling of t-PA levels is probably due to release from the vessel walls induced by the stress of childbirth and may be responsible for the drop of the PAI 1 activity and antigen levels to about half the levels found at term. No differences were observed for u-PA and PAI 2 levels and for PA activity. Three to five days after delivery the PAI activity and t-PA and PAI 1 antigen levels were not significantly different from control values, but the u-PA and PAI 2 levels were still significantly elevated, whereas the PA activity was significantly decreased. Because u-PA half-lives are relatively short,⁴⁴ we have to assume that the increased production and release and/or the decreased clearance of u-PA persisted for several days after delivery. In previous work the rapid decline in PAI activity after delivery was explained by the arrest of PAI release from placental tissue into the circulation after the expulsion of the placenta.⁹ The persistence of PAI 2 suggests either that its main site of synthesis in pregnancy and after delivery is not the placenta or that its in vivo half-life is on the order of several days. In contrast, the rapid decrease in PAI activity and PAI 1 antigen levels after delivery might suggest that PAI 1 is produced by the placenta and that it has a short in vivo half-life. The latter is in accordance with the observations of Colucci et al on the short PAI half-life in rabbits.⁴⁵

We found that the PA activity remained essentially constant during pregnancy but was slightly decreased three to five days after delivery. Our results differ from those of Arias et al¹³ who observed a significant increase in the whole blood fibrinolytic activity in pregnancy and post partum and from most other studies reporting a significant decrease in the

fibrinolytic activity of euglobulins.⁴⁻¹² Measurement of the fibrinolytic activity in euglobulin precipitates, however, has several drawbacks: (1) u-PA precipitates only partially in the euglobulins; (2) during pregnancy, the fibrinogen levels increase almost twofold and thus prolong the euglobulin clot lysis time; and (3) PAIs precipitate partially in the euglobulins (unpublished observations) and thereby affect the fibrinolytic assay. It is therefore evident that the results of fibrinolytic activity measurements in pregnancy are critically dependent on methodology, particularly on whether the activity is measured in whole blood, plasma, or euglobulins. The increased levels of fibrin degradation products during

pregnancy measured by Fletcher et al¹⁴ indicate that the +ibrinolytic system remains functionally active and do not support the hypothesis that its activity decreases significantly during pregnancy.

Our study demonstrates that the changes in the fibrinolytic system during pregnancy are much more complex than hitherto assumed. The physiological meaning of and the mechanisms inducing these changes are at present obscure.

Effect of Recombinant Human Tumor Necrosis Factor on the Colony Growth of Human Leukemia Progenitor Cells and Normal Hematopoietic Progenitor Cells

By Takuhei Murase, Tomomitsu Hotta, Hidehiko Saito, and Ryuzo Ohno

The effects of recombinant human tumor necrosis factor (rH-TNF) on the colony growth of human leukemia progenitor cells (L-CFU), granulocyte-macrophage progenitor cells (CFU-GM), and erythroid progenitor cells (BFU-E) were studied. L-CFU was assayed with leukemia cells obtained from patients with acute myelogenous leukemia. CFU-GM and BFU-E were assayed with bone marrow cells obtained from hematologically normal donors and patients with acute leukemia or non-Hodgkin's lymphoma in complete remission. A dose-dependent growth inhibition of L-CFU as well as CFU-GM and BFU-E was observed by rH-TNF at

concentrations of 1 to 100 U/mL. The inhibitory effect on L-CFU was significantly greater than that on CFU-GM. No correlation was observed between the inhibitory effect on L-CFU and the number of colonies formed in the cultures without rH-TNF. Preincubation of the progenitor cells in culture medium containing 20% fetal calf serum with up to 1,000 U/mL of rH-TNF for 24 hours did not result in the inhibition of colony growth of L-CFU or CFU-GM. The inhibitory effect of rH-TNF was neutralized by an anti-rH-TNF murine monoclonal antibody.

TUMOR NECROSIS factor (TNF) was discovered by Carswell et al¹ in the sera of mice that had been primed with bacillus Calmette-Guerin and subsequently challenged with endotoxins and is known to be associated with in vivo and in vitro killing of tumor cells.¹⁻⁵ Although early studies indicated that TNF had no effect on nontransformed culture cells,^{4,5} some investigators reported that TNF showed cytotoxic activities against a certain subpopulation of mouse and human lymphocytes.^{6,7} All of these previous studies on TNF, however, were conducted with crude or partially purified TNF. Therefore, the possible presence of other cytokines such as interferon has remained a concern.⁸

Recently, the gene for human TNF has been cloned and expressed in *Escherichia coli*,^{9,10} and the product of this expression was isolated in a pure form and shown to produce necrosis of murine tumors in vivo. Using the recombinant TNF from different sources, we¹¹ and others¹²⁻¹⁴ found that recombinant human TNF (rH-TNF) suppressed the in vitro colony growth of human hematopoietic progenitor cells. In the present study we have investigated whether TNF shows a selective cytotoxicity on human hematologic malignancies and tested the effect of rH-TNF on the in vitro colony growth of human leukemia progenitor cells (L-CFU), granulocyte-macrophage progenitor cells (CFU-GM), and erythroid progenitor cells (BFU-E). We found that rH-TNF inhibited the colony growth of L-CFU, CFU-GM, and BFU-E in a dose-dependent manner and the inhibitory effect of rH-TNF was significantly greater on L-CFU than on CFU-GM at the concentration of 100 U/mL.

MATERIALS AND METHODS

Leukemia cells and bone marrow mononuclear cells. For the L-CFU colony assays, leukemia cells were obtained from 48 patients with acute myelogenous leukemia (AML). Bone marrow or peripheral blood containing more than 80% leukemia cells was drawn and anticoagulated with preservative-free heparin. For the CFU-GM assays, bone marrow was drawn from ten hematologically normal donors and 12 patients with AML, acute lymphoblastic leukemia (ALL), or non-Hodgkin's lymphoma (NHL) in complete remission (CR). For the BFU-E assays, bone marrow was obtained from 11 hematologically normal donors and three patients with NHL in CR. All procedures were performed with informed consent.

Assays for L-CFU and CFU-GM. To compare the effects of rH-TNF on L-CFU and CFU-GM, they were assayed under the same experimental conditions according to the method described by Minden et al¹⁵ with a slight modification. Leukemia cells or bone

marrow mononuclear cells were separated from RBC and mature granulocytes by Ficoll-Conray gradient centrifugation (400 g, 30 minutes) and depleted of T lymphocytes by a second Ficoll-Conray centrifugation after rosetting with 2-aminoethylthiuronium bromide-treated sheep RBC according to the method described by Madsen et al.¹⁶ The cells remaining in the interface were washed twice and plated in 0.5 mL of culture medium containing 0.3% agar (Difco Laboratories, Detroit), α -medium (GIBCO, Grand Island, NY), 20% fetal calf serum (FCS, GIBCO), 10% conditioned medium prepared with phytohemagglutinin-stimulated leukocytes as a source of colony-stimulating activity, and 1% diluted rH-TNF. Cultures containing 1×10^4 to 2×10^5 leukemia cells for the L-CFU assay or 1×10^5 bone marrow mononuclear cells for the CFU-GM assay were incubated for nine to 11 days at 37 °C in 5% CO₂ in air. All cultures were performed in triplicate. Each agar disk was transferred onto a slide glass, fixed, and stained with Harris' hematoxylin. Colonies (>40 cells) were counted under a microscope. In some experiments, cells were simultaneously tested that had been depleted of adherent cells before the T cell depletion by two cycles of adherence to plastic dishes pretreated with FCS overnight. In each experiment of L-CFU, some colonies were picked up with a fine Pasteur pipette and stained with May-Grünwald-Giemsa stain, and their blastic nature was confirmed by observing their morphology. In some experiments, cells at the same concentration as that for semisolid culture in α -medium with 20% FCS were preincubated with up to 1,000 U/mL of rH-TNF for 24 hours at 37 °C in 5% CO₂ in air, then washed three times, and subsequently assayed for L-CFU or CFU-GM. In another experiment, cells were used that had been frozen in a programmed freezer in the medium containing 10% dimethyl sulfoxide and 10% FCS and preserved at -196 °C.

Assays for BFU-E. One $\times 10^5$ unfractionated bone marrow mononuclear cells were plated in 0.5 mL of culture medium containing 0.3% agar, α -medium, 30% FCS, 1% bovine serum albumin (BSA, Sigma Chemical Co, St Louis), 2 U/mL erythropoietin (Connaught Laboratories, Willowdale, Ontario, Canada), and 1%

diluted rH-TNF. All cells were freshly prepared. After incubation for 14 days, each culture was stained with 3,3'-diaminobenzidine tetrahydrochloride, and colonies consisting of 100 or more diaminobenzidine-positive cells were counted under a microscope.

rH-TNF. rH-TNF was kindly provided by Asahi Chemical Industry Co, Ltd, Tokyo. The rH-TNF was produced in *E coli* that expressed the gene encoding human TNF that had been identified in a human genomic DNA library¹⁷ by using a cloned cDNA encoding a portion of rabbit TNF as a probe.¹⁰ The TNF consisted of 155 amino acids with a molecular weight of 17,000 on sodium dodecyl sulfate-polyacrylamide gel electrophoresis. It has over 99% purity and a specific activity of 2.2×10^6 U/mg protein. The unit was designated as the reciprocal of dilution that killed 50% of the TNF-sensitive L-M cells which were derived from clone 929 mouse L cells. rH-TNF was diluted with a diluent consisting of 5 mmol/L phosphate buffer (pH 7.4), 0.15 mol/L NaCl, and 0.1% gelatin and added to the culture medium shortly before plating. The dilution was prepared freshly before each experiment.

Neutralization of rH-TNF activity by anti-rH-TNF monoclonal antibody. One hundred microliters of rH-TNF (10^5 U/mL) was first incubated with 13 μ L of anti-rH-TNF murine monoclonal antibody (MoAb) (30 mg/mL, subclass IgG1, provided by Asahi Chemical Industry Co)¹⁸ for one hour at 37 °C. Controls included incubation of the MoAb without rH-TNF and incubation of purified normal mouse IgG (Zymed Laboratories, San Francisco) with rH-TNF. These mixtures were added to the culture medium just before plating.

Statistical analysis. Statistical analysis was done by Student's *t* test.

RESULTS

Effect of rH-TNF on the colony growth of L-CFU. L-CFU grew from the leukemia cells of 31 out of 48 patients studied with AML. Ten cases among them gave sufficient numbers of colonies (>30 colonies/plate) and were selected for further study. At concentrations of 1 to 100 U/mL of rH-TNF, a dose-dependent inhibition of L-CFU colony growth was found. The suppressive effect was statistically significant in nine out of ten cases at 100 U/mL of rH-TNF (Table 1). Although the extent of suppression varied among the cases tested, it showed no correlation with the number of

colonies of the control cultures grown without rH-TNF. At the concentrations of 1, 10, and 100 U/mL of rH-TNF, the mean percent inhibitions were $14\% \pm 9\%$ (mean $\pm$ SD), $50\% \pm 27\%$, and $72\% \pm 27\%$ respectively.

Effects of rH-TNF on the colony growth of CFU-GM. All of the ten hematologically normal bone marrows and 11 of 12 bone marrows from patients with AML, ALL, or NHL in CR gave sufficient numbers of colonies (>30 colonies/plate) for the study of CFU-GM. At concentrations of 1 to 100 U/mL of rH-TNF, a dose-dependent inhibition of CFU-GM colony growth was found. The suppressive effect was statistically significant in 18 of 21 cases at 100 U/mL of rH-TNF (Table 2 and 3). The colonies grown from bone marrow mononuclear cells of patients with AML, ALL, or NHL in CR were regarded as normal CFU-GM based on the morphological features of colony-composing cells with normal differentiation into neutrophils, eosinophils, or monocytes. At all the concentrations tested, the extent of inhibition on CFU-GM from patients with AML, ALL, or NHL in CR was similar to that on CFU-GM from hematologically normal donors. At the concentrations of 1, 10, and 100 U/mL of rH-TNF, the mean percent inhibitions were $15\% \pm 13\%$ (mean $\pm$ SD), $33\% \pm 11\%$, and $44\% \pm 12\%$ for the former groups and $15\% \pm 13\%$, $30\% \pm 11\%$, and $48\% \pm 7\%$ for the normal donors. At the concentration of 100 U/mL, the suppressive effect of rH-TNF on L-CFU was significantly greater than on CFU-GM from hematologically normal donors ($P = .018$) or CFU-GM from patients with AML, ALL, and NHL in CR ($P = .010$) (Fig 1). When the effect of rH-TNF on L-CFU or CFU-GM was tested after the depletion of adherent cells, a similar degree of suppression was observed, which suggests that TNF was as effective a suppressor either in the absence or presence of adherent cells (data not shown). For the leukemia cells or the bone marrow cells that had been first preincubated with up to 1,000 U/mL of rH-TNF for 24 hours, depleted of rH-TNF by washing and then plated for the assay, no significant suppression of L-CFU or CFU-GM was observed. Figure 2 illustrates a representative experiment among four tests; two

of L-CFU and two of CFU-GM. Almost equal levels of L-CFU or CFU-GM suppression were observed for the fresh and the cryopreserved cells from the same donors (data not shown).

Effects of rH-TNF on the colony growth of BFU-E. Eight of 11 hematologically normal bone marrows and two of three bone marrows from patients with NHL in CR gave sufficient numbers of colonies (>30 colonies/plate). At concentrations of 1 to 100 U/mL of rH-TNF, a dose-dependent inhibition of the BFU-E colony growth was found. The suppressive effect was statistically significant in all ten cases at 100 U/mL of rH-TNF (Table 4). At the concentrations of 1, 10, and 100 U/mL of rH-TNF, the mean percent inhibitions were $23\% \pm 21\%$ (mean ± SD), $62\% \pm 24\%$, and $97\% \pm 4\%$ respectively.

Neutralization of the rH-TNF activity by anti-rH-TNF MoAb. The suppressive effect of rH-TNF on L-CFU or

CFU-GM at concentrations of 50 and 500 U/mL was neutralized by a murine MoAb specific to rH-TNF and not by normal mouse IgG, which indicates that the inhibition was caused by the rH-TNF and not by a contaminant. Neither normal mouse IgG alone nor the MoAb alone showed any effect on L-CFU or CFU-GM. Figure 3 illustrates a representative experiment among four tests; two of L-CFU and two of CFU-GM.

DISCUSSION

The present study shows that rH-TNF suppresses the in vitro colony growth of human L-CFU, CFU-GM, and BFU-E. Because the suppressive effect was neutralized by a murine MoAb specific to rH-TNF, the effect is considered to derive from rH-TNF itself. At the concentration of 100 U/mL, although the extent of inhibition on L-CFU varied considerably among patients (26% to 100%), the suppressive

Fig 1. Comparison of the effects of rH-TNF on the colony growth of L-CFU and CFU-GM. The mean number of colonies from ten experiments on L-CFU from patients with AML (—●—), that from ten experiments on CFU-GM from hematologically normal donors (---○---), and that from 11 experiments on CFU-GM from patients with AML, ALL, and NHL in CR (—■—), which are expressed as a percentage of the number of colonies in each control culture without rH-TNF are shown. At the concentrations of 100 U/mL of rH-TNF, the inhibitory effect on L-CFU was significantly greater than that on CFU-GM from hematologically normal donors ($P = .018$) or CFU-GM from patients with AML, ALL, or NHL in CR ($P = .010$).

effect of rH-TNF on L-CFU was significantly greater than that on CFU-GM. No relationship was found between the extent of suppression of L-CFU and the number of colonies grown in the absence of rH-TNF. We did our best to perform these experiments under the same conditions for an accurate comparison of the effect of rH-TNF on L-CFU and CFU-GM. We defined L-CFU as colonies that had grown out of cells from bone marrow or peripheral blood containing more than 80% leukemia cells and the colony-composing cells that showed morphological characteristics of the original leukemia cells. It should be noted, however, that the morphological characteristics may not be enough for the evidence that the colony-composing cells in L-CFU were truly leukemic.

Fig 2. Effect of rH-TNF on the colony growth of L-CFU by preincubation study. No significant suppression was seen when 1×10^4 leukemia cells in 0.5 mL of α -medium with 20% FCS had been preincubated with rH-TNF for 24 hours at 37 °C in 5% CO₂ in air prior to the start of culture (hatched bars), whereas the suppressive effect of rH-TNF was evident when it was continuously added during the whole culture period (blank bars).

Therefore, we tested CFU-GM from patients with hematologic malignancies in CR under the same conditions. The results were almost the same as those on CFU-GM from normal donors, although, again, the morphological characteristics may not be enough for the evidence that the colony-composing cells in CFU-GM from patients with AML, ALL, or NHL in CR were truly normal.

Most previous studies using crude or partially purified TNF demonstrated that TNF did not affect nontransformed cells of mice or humans. However, our results indicate that TNF has inhibitory effects on normal human hematopoietic progenitor cells as well as leukemia progenitor cells. Degliantoni et al¹² independently found that rH-TNF from a different source suppressed the colony growth of CFU-GM while they were trying to prove that natural killer (NK) cell-derived hematopoietic colony-inhibiting activity and

Fig 3. Neutralization of the rH-TNF activity by anti-rH-TNF MoAb. rH-TNF at 50 or 500 U/mL was incubated with anti-rH-TNF murine MoAb (hatched bars) or with normal mouse IgG (blank bars) for one hour at 37 °C and added to the L-CFU cultures just before plating.

NK cytotoxic factor are probably identical with TNF. Playfair et al⁶ reported that crude TNF showed cytotoxic activities against a certain subpopulation of mouse lymphocytes. Umeda et al⁷ observed a cytotoxic effect of TNF on lectin-activated human lymphocytes and the specific binding of TNF to the target cells, which indicated that normal lymphocytes also possessed TNF receptors on their cell surfaces. Recently, Beutler et al¹⁹ have reported the possible identity of TNF and the macrophage-secreted factor cachectin, which can bind to the receptors present on several normal murine tissues. They found, however, no detectable quantities of cachectin receptors on erythrocytes and lymphocytes, even though Sassa et al²⁰ from the same group had reported the inhibition of growth and the differentiation of transformed erythroid precursor cells (Friend's leukemia cells) by crude cachectin. On the other hand, some investigators have reported the ability of rH-TNF to stimulate the growth of several normal human cell lines.^{21,22}

After this paper had been submitted for publication, Broxmeyer et al²³ reported the suppressive effect of two types of human TNF (purified and recombinant) on bone marrow

hematopoietic progenitor cells from normal donors and patients with leukemia. They found that the suppression of leukemia cluster-forming cells by TNF was stronger than that of CFU-GM. These results appear to be consistent with ours. In the present study, the suppressive effect of rH-TNF on BFU-E appeared to be stronger than that on CFU-GM. However, we think, these results for BFU-E are unable to be simply compared with those for L-CFU or CFU-GM because these assays were done under different experimental conditions such as the FCS concentration,²² the incubation period, and the presence or absence of BSA.

The cloning of the gene for human TNF and subsequent recombinant technology have permitted the production of rH-TNF in large quantities for clinical use, and a phase I study has already been conducted in Japan. From our experience in the phase I study at our hospital, 100 U/mL of rH-TNF is a concentration that is easily attainable in patients. Besides, even 1 U/mL rH-TNF showed mild but definite suppressive effect on L-CFU, CFU-GM, and BFU-E in vitro. However, because the preincubation of the progenitor cells with up to 1,000 U/mL of rH-TNF for 24 hours did not result in the significant suppression of the colony growth of L-CFU and CFU-GM, the suppressive effect appeared to be cytostatic. In contrast, Broxmeyer et al²³ reported that 60 minutes of pulse exposure of normal bone marrow cells to TNF produced significant suppression of the colony growth of CFU-GM, BFU-E, and multipotential progenitor cells. Their results are not consistent with ours and suggest that the suppressive effect of TNF on hematopoietic progenitor cells is cytotoxic. This discrepancy is difficult to explain, although it may be due to differences in experimental conditions such as the presence or absence of FCS during pulse exposure time.

In conclusion, whether the suppressive effect is cytotoxic or cytostatic, rH-TNF has greater suppressive effect on L-CFU than that on CFU-GM in vitro. rH-TNF may be of value in the treatment of AML, although it may cause some hematologic toxicity because of the suppressive effect on normal hematopoietic progenitor cells.

ACKNOWLEDGMENT

We thank Dr Kiyoji Kimura for his valuable advice and Sayoko Sugiura and Tomoko Kozawa for their excellent technical assistance.

A New Variant of the α Subunit of Spectrin in Hereditary Elliptocytosis

By S. Lambert and S. Zail

A kindred is described in which two brothers with a poikilocytic variant of hereditary elliptocytosis (HE) were found to have a defect of spectrin dimer association and a decreased spectrin-band 3 ratio. Two-dimensional gel electrophoresis of limited tryptic digests of their spectrin revealed decreased amounts of the α I domain when compared with control digests and the appearance of two major peptides with mol wts of 43,000 and 42,000 and isoelectric points (5.75 to 5.85) more basic than the α I domain. Tryptic digests of spectrin from the asymptomatic mother of the two brothers were normal. Immunoblots of the two-dimensional gels using an antiserum to the α I

domain revealed that the 43,000- and 42,000-dalton peptides were derived from the α I domain, along with a series of lower mol wt peptides, some of which were below the detection limits of Coomassie blue-stained gels. Limit chymotryptic maps of ^{125} I-labeled tryptic peptides confirmed that the 43,000- and 42,000-dalton peptides were derived from the α I domain. This kindred represents a new structural variant of spectrin in HE in that the major abnormal tryptic peptides derived from the α I domain have lower mol wts and more basic isoelectric points than hitherto described.

© 1987 by Grune & Stratton, Inc.

SEVERAL MOLECULAR abnormalities affecting the α I domain of spectrin have been described in mild hereditary elliptocytosis (HE), which is the most prevalent form of hereditary elliptocytosis, and in the closely related condition of hereditary pyropoikilocytosis (HPP).¹⁻³ The α I domain constitutes the N-terminal head region of the α chain, which together with the phosphorylated β I domain of the β chain is involved in spectrin tetramer and higher oligomer assembly.²⁻⁴ Molecular lesions of these domains lead to defective tetramer assembly and are thought to be causally related to the genesis of the elliptocytes and poikilocytes characteristic of HE and HPP.³

A feature of patients with mild HE or HPP who have structural defects of the α I domain is that limited tryptic digests of spectrin reveal a decrease or complete absence of this domain (80,000 daltons) on two-dimensional isoelectric focusing/sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE).^{2,3} In one structural variant, there is a reciprocal increase in a 74,000-dalton peptide, HE [Sp $\alpha^{1/74}$] and HPP [Sp $\alpha^{1/74}$],^{5,6} and in another there is an increase in several tryptic peptides of 46,000 daltons with isoelectric points between 5.25 and 5.35 and a peptide of 17,000 daltons with an isoelectric point of 5.4, HE [Sp $\alpha^{1/46}$] and HPP [Sp $\alpha^{1/46}$].^{5,7} (For the nomenclature of spectrin α chain defects, see ref. 3.) Two kindreds with HPP described by Knowles and co-workers⁸ and two kindreds with HE described by Marchesi and colleagues⁹ have increased amounts of tryptic peptides with mol wts of 50,000 and 21,000 and similar isoelectric points to the abnormal peptides of HPP [Sp $\alpha^{1/46}$]. A third structural variant in which the abnormal peptide has a mol wt of 65,000 has been described only in HE: HE [Sp $\alpha^{1/65}$].^{10,11}

In this study, we report a new variant of spectrin in a kindred with a poikilocytic variant of HE in which the α I domain is diminished on tryptic digestion, with the appearance of two major abnormal peptides with mol wts of 43,000 and 42,000, and in which the isoelectric points are considerably more basic (pI 5.75 to 5.85) than previously described. These peptides, together with several minor lower mol wt peptides, are shown to be derived from the α I domain, using immunoblots probed with an antibody to the α I domain. Limit chymotryptic maps of the 43,000- and 42,000-dalton peptides confirm that they are derived from the α I domain.

METHODS

Patients. The proband, M.S., aged 35 years, is a black South African miner who was initially investigated in 1982 after admission to hospital for abdominal pain. He improved with symptomatic therapy and has since had no recurrence of his symptoms. Both he and his younger brother (A.S.) (aged 30 years) were splenectomized in infancy, but details of these admissions are not available. Examination of the blood smears of both A.S. and M.S. revealed a predominance of elliptocytes (40% to 50%), with a considerable number of small, densely staining poikilocytes and some budding RBCs (Fig 1A). RBC indices for M.S. were: hemoglobin 15.0 g/dL; hematocrit 42%; MCHC 36 g/dL; MCV 69 fL; reticulocyte count 2.0%. RBC indices for A.S. were: hemoglobin 15.5 g/dL; hematocrit 43%; MCHC 36 g/dL; MCV 68 fL; reticulocyte count 4.0%. Autohemolysis for both patients varied between 30% and 40% and was partially corrected by glucose. Osmotic fragility of fresh RBCs was increased, with a median cell fragility of 0.48 g/dL NaCl in both patients (normal range 0.40 to 0.45 g/dL). Serum vitamin B₁₂ and RBC and serum folate were normal. Hematologic parameters in the mother, who was asymptomatic and has normal RBC morphology (Fig 1B) were within normal limits (hemoglobin 14.7 g/dL; MCV 89 fL; MCHC 34 g/dL; reticulocyte count 2.0%). The father is deceased. A.S. has a child who is unavailable for study. Incubation of venous blood of both M.S. and A.S. [within 6 hours of collection on ice in EDTA or acid-citrate-dextrose (ACD)] at 47 °C for 15 minutes leads to marked budding, distortion, and crenation of RBCs (Fig 1C). In contrast, no morphological alterations were seen in a normal control (Fig 1D) or in the mother (not shown).

Preparation of spectrin extracts. Blood was obtained from patients and controls after informed consent and approval of the

Fig 1. Photomicrograph of peripheral blood smears of (A) fresh RBCs of A.S.; (B) fresh RBCs of the mother of A.S.; (C) RBCs of A.S. heated for 15 minutes at 47°C; (D) RBCs of a normal control subject heated for 15 minutes at 47°C.

project by the Research Committee of the South African Institute for Medical Research. Venous blood was collected in ACD, kept on ice, and processed within 12 hours. Erythrocyte ghosts were prepared by hypotonic lysis of washed erythrocytes at 4°C in 30 vol of 10 mmol/L of Tris-HCl, 1 mmol/L of EDTA, 25 µg/mL of phenylmethylsulfonyl fluoride (PMSF) (dissolved at 25 mg/mL of isopropanol), pH 7.6, and centrifugation for 15 minutes at 30,000 g. The ghosts were washed four to five times in lysis buffer and then once in 0.25 mmol/L of EDTA, pH 8.0. Extracts of spectrin for tryptic digestion were obtained by incubating the ghosts (2 to 3 mg/mL) in 0.25 mmol/L of EDTA, pH 8.0, for 30 minutes at 37°C, and the supernate was collected after centrifugation at 150,000 g for 30 minutes at 4°C. Extracts of spectrin for determination of the proportion of spectrin dimers and tetramers in native membranes were obtained by incubating ghosts (2 to 3 mg/mL) in 0.25 mmol/L of EDTA, 25 µg/mL of PMSF, 2 µg/mL of pepstatin, 2 µg/mL of leupeptin, pH 8.0, for 24 hours at 0°C and centrifugation as before.

Tryptic digestion of spectrin. Spectrin (37°C) extracts were adjusted to a concentration of 40 mmol/L of Tris HCl, 20 mmol/L of Na acetate (pH 7.4) containing 1 mmol/L of dithiothreitol (DTT), and digested with 1:100 wt/wt L-(tosylamido 2-phenyl) ethylchloromethyl ketone-trypsin (231 U/mg, Worthington Biochemical, Freehold, NJ) for 18 hours at 0°C. Protein concentration was determined with a protein assay kit (Bio-Rad Laboratories, Richmond, CA) using bovine serum albumin (BSA) as standard. Digestion was stopped by addition of 1 mmol/L of PMSF and snap-freezing in solid CO₂ and acetone. Samples were lyophilized and stored at -20°C.

Protein electrophoresis. Analytical SDS-PAGE on tube gels (4% acrylamide) was performed using the conditions of Fairbanks and colleagues.¹² One-dimensional gels stained with Coomassie blue were scanned with a recording densitometer (PU 8800, Pye Unicam, Cambridge, England). The areas under the spectrin and band 3 peaks were cut out and weighed and the spectrin-band 3 ratio was determined. Samples digested with trypsin were reconstituted in 9.5 mol/L of urea, 2% wt/vol NP-40, 5% mercaptoethanol, and 2%

ampholytes, pH 4.0 to 6.5 (Pharmalyte, Pharmacia Fine Chemicals, Uppsala, Sweden). Samples (150 to 200 µg of protein) were electro-focused for 6,500 V/h with a maximum of 400 V in 4% acrylamide gels containing 6.25% carrier ampholytes, pH 4.0 to 6.5, as described by O'Farrell.¹³ Equilibrium was reached under these conditions since electrofocusing for 10,000 V/h had no effect on the separation pattern. Second dimension SDS-PAGE was performed on 4% to 15% SDS acrylamide slab gels according to the method of Laemmli¹⁴ and fixed and stained with 0.1% Coomassie blue G-250 in 25% isopropanol, 10% acetic acid. Peptide mol wts were derived from logarithmic plots of mol wt against mobility, using as markers the mol wts assigned to erythrocyte membrane proteins by Lux.¹⁵ Preliminary experiments showed that these determinations correlated closely with mol wts derived using a commercial preparation of low-mol wt markers (Pharmacia). Electrophoretic transfer of fixed and stained gels was carried out according to the method of Jackson and Thompson.¹⁶ Gels were extensively destained in 10% acetic acid, washed in four changes of water, and incubated at 4°C in 0.025 mol/L Tris, 0.192 mol/L of glycine, and 10 g/L SDS for 2 hours. Proteins were then transferred using the method of Towbin and co-workers¹⁷ for 16 hours at 7.5 V/cm. Nitrocellulose blots were blocked with 3% gelatin at room temperature for 1 hour and treated essentially according to the method of Lawler and colleagues,¹¹ using an antiserum raised against the α I domain of normal spectrin (kindly supplied by Dr J. Lawler, St Elizabeth's Hospital, Boston). All wash buffers (except directly before color development) contained 0.05% Tween, and color development was performed using 3,3'-diaminobenzidine tetrahydrochloride as substrate. Blots were photographed using reflected light through a Wratten 47B gelatin filter to remove interference from Coomassie blue-stained peptides. Immunoblots of unfixed, unstained gels gave essentially similar blots but did not allow as direct a comparison of the immunoblot with the Coomassie blue-stained gel; therefore, immunoblots of fixed, stained gels were used preferentially.

¹²⁵I-peptide mapping. Coomassie blue-stained proteins were cut from the two-dimensional polyacrylamide gels and labeled with ¹²⁵I (557 mCi/mL, Amersham International, Amersham, England) by the technique of Elder and co-workers.¹⁸ The iodinated gel slices were digested with 50 µg of α -chymotrypsin (Worthington Biochemical) in 1 mL of 50 mmol/L of ammonium bicarbonate (pH 8.0) for 25 hours at 37°C. The supernates were lyophilized. Autoradiographs of two-dimensional separations on cellulose plates (Merck, Darmstadt, F.R.G.) were obtained as described by Speicher and co-workers.¹⁹

RESULTS

SDS-PAGE of isolated membranes. Spectrin-band 3 ratios in M.S. and A.S. were 0.70 and 0.74, respectively. The ratio in eight normal controls was 1.02 ± 0.06 . SDS-PAGE of isolated membranes of M.S. and a normal control subject is shown in Fig 2B and 2A, respectively. Membrane proteins other than spectrin appeared normal in M.S. and A.S.

Nondenaturing gel electrophoresis of 0°C spectrin extracts. The proportion of spectrin dimers in 0°C membrane extracts (as a percentage of the total dimer plus tetramer pool and excluding oligomeric forms of spectrin) was increased to 25% in M.S. and 30% in A.S. (Table 1). The percentage of dimers in the mother of the patients was 10%, which is at the upper limits of the range found in 10 normal control subjects.

Two-dimensional isoelectric focusing/SDS-PAGE of limited tryptic digests of spectrin. Limited tryptic digests of

Fig 2. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of isolated RBC membranes of (A) a normal control subject; (B) patient M.S.

spectrin obtained from normal control subjects produced a pattern of peptides on two-dimensional SDS-PAGE similar to that described by others. A Coomassie blue-stained control digest (which was always run concurrently with patients' samples to identify minor variations in experimental conditions) is shown in Fig 3A, and the domains of spectrin are labeled according to the nomenclature of Speicher and co-workers.¹⁹ The position of the β IV peptide deserves comment. We found this peptide consistently in a position above the α I domain, in contrast to some workers^{2,8,9} who found it positioned below the α I domain. The β IV peptide has been found variably positioned by other workers,³ who, when using digestion conditions identical to that used in the present study, also found the peptide positioned above that of the α I domain.⁵

A structural polymorphism of the α II domain of spectrin, based on variations in mol wt and/or isoelectric point is present in American²⁰ and South African blacks and must be identified in both control and patient digests to distinguish any such variation from putative abnormal peptides in

patients' digests. The control digests in Fig 3A show a homozygous type 2 α II domain variant (3,000 dalton increase in mol wt, and more basic isoelectric point than does the common type I variant), and the representative peptides and their proteolytic products are ringed and joined by solid lines. Apart from the polymorphic variations in the α II domain, tryptic peptides maps identical to that shown in Fig 3A were obtained in more than 40 black control subjects. Figure 3C shows the corresponding limit tryptic digest of spectrin in the propositus, M.S. There is a marked reduction in the intensity of staining of the 80,000-mol wt α I domain (pI 5.35 to 5.45) and the generation of abnormal peptides with mol wts of 43,000 and 42,000 (large arrows in Fig 3C). These peptides have isoelectric points ranging between 5.75 to 5.85 that overlap the pI of the β IV domain. A faintly staining doublet of peptides with mol wts of 21,000 and 20,000 and a peptide with a mol wt of 16,000 are also shown at arrows in Fig 3C and represent abnormal peptides in M.S. In more than 40 black control subjects, the peptides with mol wts of 43,000, 42,000, 21,000, 20,000, and 16,000 were not observed, making it highly unlikely that the pattern observed in A.S. and M.S. represents a structural polymorphism in black subjects. The polymorphic α II-domain peptides and proteolytic products in M.S. show the features of a type 1/4 double heterozygote and are ringed in Fig 3C to distinguish them from the abnormal peptides.

An immunoblot of the control limited tryptic digest, probed with an antiserum to the α I domain, is shown in Fig 3B. An area corresponding to the α I domain and an overlapping peptide of 76,000 daltons stains most intensely, whereas a series of lower mol wt peptides of similar isoelectric point to the α I domain show less intense staining. These latter peptides are not visible on the corresponding Coomassie blue-stained gel in Fig 3A. A similar pattern of staining of the α I domain and lower mol wt peptides of similar isoelectric point are seen on the immunoblot of M.S. shown in Fig 3D. In addition, however, the abnormal peptides of mol wts of 43,000, 42,000, 21,000, 20,000, and 16,000 seen in the Coomassie blue-stained gel are also stained on the immunoblot (large arrows in Fig 3D) suggesting that these peptides are derived from the α I domain. Several other abnormal peptides also stained less intensely on the immunoblot of M.S. and are not visible on the Coomassie blue-stained gel. These are shown (small arrows) in Fig 3D. The immunoblot reveals that the peptides with mol wts of 21,000, 20,000, and 16,000 have multiple isoelectric points. In addition, one peptide shown (asterisk in Fig 3C) was not present in control digests and did not appear to be derived from the α I domain because it did not stain in the corresponding immunoblot. Coomassie blue-stained gels and immunoblots of A.S. were identical to those of M.S. Limited tryptic digests of the mother did not show any abnormality (not shown).

¹²⁵I-Peptide maps of the α I domain and the 43,000- and 42,000-dalton peptides. Further evidence that the major abnormal peptides of 43,000 and 42,000 daltons were fragments of the α I domain of spectrin in patient M.S. was shown by high-resolution ¹²⁵I-peptide maps of these tryptic peptides. Limit chymotryptic ¹²⁵I-peptides of the 43,000- and 42,000-dalton peptides (Fig. 4C and D) are contained within the

Fig 3. Two-dimensional isoelectric focusing/sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of tryptic digests of spectrin extracts of a normal control subject (A and B) and patient M.S. (C and D). Coomassie blue-stained and fixed gels are shown on the left (A and C); the immunoblots (B and D) of the stained and fixed gels are shown on the right. An antiserum against the α I domain was used to probe the blots. The position of some of the tryptic domains of spectrin are indicated. Large arrows in C and D show the abnormal peptides generated in digests of M.S. present in both the Coomassie blue-stained gels and the immunoblot. The small arrows in D depict minor peptides derived from the α I domain but are visible only on the immunoblot. The peptide (asterisk; C) is not present in control digests and does not stain on the corresponding immunoblot. The ringed peptides in A and C represent the polymorphic α I domain and its proteolytic products.

map of ^{125} I-peptides of the remnant α I domain of spectrin of M.S. (Fig 4B). Two ^{125} I-peptides (arrows) in this map of the α I domain of M.S. (Fig 4B) showed altered mobility when compared with the map of the control α I domain (Fig 4A). These changes were not consistent in different limit chymotryptic maps of the α I domain of M.S., A.S., and other control subjects, however, and are therefore not regarded as being of significance.

DISCUSSION

The affected members of this kindred show a significant degree of elliptocytosis, with considerable numbers of dense,

bizarre poikilocytes (Fig 1A). They also have a mild defect of spectrin self-association, as manifested by an increase in the proportion of spectrin dimers in 0 °C low ionic strength extracts of isolated membranes. We believe that these patients should probably be classified as a poikilocytic variant of HE,⁹ rather than HPP, since the degree of elliptocytosis is in excess of that seen in HPP. Moreover, the altered heat stability is more consistent with HE, since the RBCs of these patients do not show gross fragmentation when heated to 47 °C. The distinction from HPP is, however, more difficult in this kindred because both patients show a decrease in the spectrin-band 3 ratio, which is a characteris-

Fig 4. Limit chymotryptic ^{125}I -peptide maps of tryptic peptides of spectrin: (A) αI domain of normal control; (B) αI domain of M.S. (C and D) 43,000- and 42,000-dalton peptides of M.S. The arrows depict peptides in the maps of the αI domains of both the control subject and M.S. that exhibit changes in mobility not consistent between different experiments and therefore not regarded as being of significance.

tic feature of HPP.²¹ The mode of transmission is unfortunately obscure, since no data are available for the father, and the mother appears clinically, functionally, and biochemically normal.

The structural abnormality of the αI domain of spectrin in patients M.S. and A.S. is associated with defective tetramer formation, as manifested by an increased proportion of dimers in native membranes, and is presumably the cause of the clinical abnormality. Defects of the αI domain of spectrin in HE and HPP manifest on limited tryptic digests of spectrin as a decrease or absence of the αI domain. This presumably reflects a conformational change in the αI domain that renders it more susceptible to proteolysis. Some kindreds with mild HE or HPP demonstrate reciprocal generation of increased amounts of a 74,000-dalton peptide,^{5,6} whereas others show increased amounts of lower mol wt peptides variously estimated at between 46,000 and 50,000 daltons and 17,000 and 21,000 daltons.^{5,7-9} In the latter group, Lawler and co-workers^{5,7} found that the 46,000-dalton peptides had isoelectric points (5.25 to 5.35) that were

acidic relative to the αI domain (pI 5.3 to 5.4), whereas the 17,000-dalton peptides focused at approximately the same pI as the αI domain. The 50,000- and 21,000-dalton peptides described by Knowles and colleagues⁸ and Marchesi and co-workers⁹ in HPP and HE, respectively, had a similar orientation. A third variant, HE[Sp $\alpha^{1/65}$] had increased amounts of a peptide of mol wt 65,000.^{9,10} In our studies, the αI domain of normal spectrin focuses at a pI of 5.35 to 5.45, which is close to that found by Lawler and co-workers,^{5,7} but the abnormal 43,000- and 42,000-dalton peptides in M.S. and A.S. have isoelectric points (5.75 to 5.85) that are clearly basic relative to the αI domain. Because we also show that the 43,000- and 42,000-dalton peptides are derived from the αI domain on the basis of their cross-reactivity with an antiserum to the αI domain (Fig 3) and their sharing of common peptides on high-resolution ^{125}I -peptide mapping (Fig 4), patients M.S. and A.S. constitute a new variant of the αI domain in HE. Other changes are also apparent in our patients. The minor abnormal peptides at 21,000, 20,000, and 16,000 focus on Coomassie blue-stained gels and immu-

noblots (Fig 3D) at isoelectric points acidic to the α I domain, with the exception of one 16,000-dalton peptide on the immunoblot that has an isoelectric point similar to that of the α I domain. The immunoblot of MS (Fig 3D) also shows fainter staining peptides (small arrows) above and below the abnormal 43,000- and 42,000-dalton peptides that may be precursors and products, respectively, of the major abnormal peptides.

While this work was in progress, two preliminary reports by Marchesi and co-workers^{22,23} appeared, describing two black families with HE in whom abnormal tryptic peptides of

50,000 daltons, derived from the α I domain but with isoelectric points more basic than the α I domain, have been found. The variant spectrin described in the present study appears to be different from that described by Marchesi and co-workers²³ in that the major abnormal tryptic peptides have a considerably lower mol wt.

Platelet Antithrombin Defect in Malignancy: Platelet Protein Alterations

By Elaine M. Sloand, Dianne M. Kenney, Francis C. Chao, Jack Lawler, and James L. Tullis

Sixty-eight patients with malignant disease were divided into two groups based on the results of the platelet antithrombin test (PAT). The normal group had a PAT clotting time ranging from 21.4 to 29.8 seconds, which was equivalent to 25% to 65% inactivation of the 2 U of thrombin added to the test system. The other group showed abnormal PAT clotting time, <21.4 seconds or <25% thrombin inactivation. The polypeptide composition of platelets from the two patient groups was analyzed by sodium dodecyl sulfate (SDS)-electrophoresis on 7.5% polyacrylamide gels. A polypeptide of 180,000 apparent mol wt was decreased or absent in both Coomassie blue- and Alcian blue-stained gels of the platelets from patients whose PAT was abnormal; this polypeptide comigrated with purified platelet thrombospondin. Tritium labeling of platelet surface glycoproteins by the periodate-borohydride method followed by two-dimensional electrophoresis was performed on platelets of seven patients with abnormal

PAT. When they were compared with ten patients with normal PAT, a glycoprotein of 140,000 apparent mol wt with a pI of 4.5 to 5.2 was decreased in platelets of all seven patients with abnormal PAT. Nitrocellulose replicas of one-dimensional gels of platelets from 13 of 14 patients with abnormal PAT showed decreased reaction with an anti-human platelet glycoprotein antiserum. Platelets of these same patients also showed a decreased or absent platelet agglutination induced by ristocetin. Patients with normal PAT had a mean agglutination slope of 1.25 ± 0.6 ($n = 26$) as compared with 0.37 ± 0.34 ($n = 26$) for the abnormal PAT group ($P < .001$). Results indicate that platelets from a subpopulation of tumor patients characterized by decreased platelet antithrombin activity have alterations in two platelet glycoproteins, identified as GPIb and thrombospondin.

© 1987 by Grune & Stratton, Inc.

THE CLOTTING ACTIVITY of α -thrombin can be neutralized by intact human platelets. This activity is referred to as platelet antithrombin.¹ Thrombin inactivation by normal platelets has been shown to be membrane dependent for two-thirds of the activity and secondary to the release of intracellular platelet fibrinogen for the other third.² A simple two-stage assay has established the normal physiologic range³ and has been used to demonstrate a decrease in platelet antithrombin activity in certain pathologic states. This includes patients with primary (congenital) deficiencies⁴ as well as patients with apparent acquired deficiency secondary to malignant states.⁵ In a separate clinical study, one third of the patients with advanced/disseminated adenocarcinomas, melanomas, and myeloproliferative disorders were found to have a consistent decrease in platelet antithrombin activity.⁶

The present study was designed to determine whether changes in platelet proteins could be correlated with abnormal platelet antithrombin activity. A group of patients with malignant disease and reduction in platelet antithrombin activity was compared with a group of patients with similar malignancies in whom thrombin inactivation by platelets was normal. The platelet proteins from these two groups of patients were analyzed by several electrophoretic and immunochemical techniques. The results demonstrate that two platelet proteins are altered in cancer patients whose platelets show defective inactivation of thrombin. One shows the characteristics of the membrane glycoprotein Ib (GPIb) and the other shows an α -granule component, thrombospondin.

MATERIALS AND METHODS

Patient population. Sixty-eight patients from the medical oncology ward of the New England Deaconess Hospital were divided into two groups on the basis of platelet antithrombin test (PAT) results. All were part of a larger clinical study involving platelet antithrombin determinations on >200 patients with advanced malignant disease.⁶ Malignancies studied included ovary, lung, colon, melanoma, and lymphoma. Patients who were receiving aspirin, nonsteroidal antiinflammatory agents, or vinca alkaloids were excluded. As established previously,⁴ results of PAT measurement

follow a bimodal distribution. Patients with abnormal PAT had a clotting time <20.5 seconds (PAT measurement is also described in the Results section). Fourteen of the 37 patients with an abnormal PAT and 15 of the 31 patients with a normal PAT were not on current chemotherapy. The members of each group who were receiving chemotherapy had equal exposure to standard agents such as fluorouridine (FUDR), cytoxan, cisplatin, 5-fluorouracil (5-FU), and adriamycin.

Platelet preparation. Venous blood was drawn from the 68 patients and from three normal individuals (healthy controls) and mixed with acid-citrate-dextrose (ACD) [National Institutes of Health (NIH), Formula A] and EDTA anticoagulant solution to yield final concentrations of 15% (vol) ACD and 5 mmol/L of EDTA. After centrifugation at room temperature at 130 g for 15 minutes, the platelet-rich plasma (PRP) was removed, a 20% vol of ACD-EDTA was added, and the platelets were pelleted by centrifugation at 1,200 g for 15 minutes. Platelets were washed twice by resuspension in Tris-buffered saline (TBS) containing 10% ACD-EDTA. Platelet aliquots used for the PAT were resuspended without anticoagulants and adjusted at 2×10^9 /mL. For electrophoresis, platelets were resuspended at 1×10^9 /mL in 67 mmol/L of Tris-HCl buffered 100 mmol/L of NaCl with 5 mmol/L of EDTA and 5 mmol/L of iodoacetamide.

Assay for platelet antithrombin activity. Platelet antithrombin activity was measured by a two-stage assay described previously.^{3,4} Washed platelets (0.5 mL) were incubated for 10 minutes at room

temperature with 0.5 mL of thrombin solution (Parke-Davis, Morris Plains, NJ) at 4 NIH U/mL. Commercial thrombin gave results comparable to those of purified human thrombin.² After incubation, 0.2 mL of the reaction mixture was added to 0.2 mL of fibrinogen (2 mg/mL) prewarmed at 37 °C for 5 minutes. The clotting time was then determined. The variation between duplicate samples averaged 0.7 seconds (range 0 to 1.5 seconds).

SDS-Polyacrylamide gel electrophoresis (PAGE). Polypeptides were fractionated by SDS-PAGE according to the procedure of Laemmli⁷ using a 7.5% polyacrylamide resolving gel and a 4% stacking gel. Washed platelets were solubilized with 3% SDS and boiled for 3 minutes and were then treated with 10 mmol/L of dithiothreitol for 1 minute at 100 °C. Equivalent protein concentrations (20 to 80 µg) were applied in each analysis of platelets from patients with normal and abnormal PAT.

Gels were stained with Coomassie blue and Alcian blue. For Alcian blue staining,⁸ polyacrylamide gels were fixed in 12.5% trichloroacetic acid for 30 minutes and were then treated for 50 minutes at room temperature with 7% periodic acid in 3% acetic acid. The fixed gels were washed twice with 200 mL of distilled water and soaked in 0.5% metabisulfite for 30 minutes. The gels were washed and stained with 1% Alcian blue (in 3% acetic acid) overnight and destained in 7% acetic acid. Standard mol wt marker proteins were: spectrin heterodimer (240,000 and 220,000) – galactosidase (130,000), phosphorylase A (94,000), albumin (68,000), glutamate dehydrogenase (56,000), creatinine kinase (40,000), and carbonic anhydrase (29,000).

Radiolabeling of surface carbohydrate moieties. Surface sialic acid residues of glycoproteins were labeled with ³H by the method of Steiner and colleagues⁹ with some modifications. Platelets washed twice in Tyrodes' solution containing 5 mmol/L of EDTA, buffered at pH 6.8 with 10 mmol/L of *N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid (HEPES) (HTE), were resuspended in a 1- to 2-mL vol of HTE at 0.5×10^9 cells/mL. Sodium periodate was added to a final concentration of 2 mmol/L, and the reaction mixture was incubated at 4 °C in darkness for 20 minutes. Unreacted periodate was removed by two washes with HTE at pH 7.6, and the platelets were resuspended in 1 to 2 mL of the same buffer. [³H]NaBH₄ (5 mCi in 50 µL of cold 0.01 mol/L of NaOH) was added to a final concentration of 500 µCi/ 0.5×10^9 platelets and incubated for 30 minutes at room temperature with periodic agitation. Radiolabeled platelets were washed twice, resuspended in HTE (pH 6.8), and extracted with 0.5% NP-40 in the presence of 5 mmol/L of iodoacetamide. Extracts of radiolabeled platelets, routinely frozen at -20 °C, were thawed and clarified by centrifugation at 1,200 g for 15 minutes and subjected to one- or two-dimensional SDS-PAGE. Polyacrylamide gels containing ³H-labeled proteins were prepared for fluorography by being impregnated in 22% (wt/vol) diphenyloxazole in dimethylsulfoxide (DMSO) as described by Bonner and Laskey.¹⁰ This technique was also used to analyze xylocaine-treated platelets (described later).

Two-dimensional gel electrophoresis. Two-dimensional isoelectric focusing-SDS-gel electrophoresis was performed by a method modified from O'Farrell.¹¹ Extracts of radiolabeled platelets were prepared for isoelectric focusing by adding solid urea and dithiothreitol to final concentrations of 9.5 mol/L and 100 mmol/L, respectively. Samples containing 20 µg of protein were applied to the isoelectric focusing gels, which were composed of 3.5% acrylamide, 3.2% Triton X-100 (Fisher Scientific, Springfield, NJ), 4% Ampholines (pH range 5 to 8), 0.4% Ampholines (pH range 4 to 6), 0.6% Ampholines (pH range 3.5 to 10), and focused for 16 hours at 400 V and for 2 hours at 1,000 V. The pH values (reflecting relative isoelectric points of separated proteins) were measured from Ampholines eluted from 5-mm slices of duplicate gels that had been focused in parallel without protein samples. Extraction with NP-40

allowed determination of the relative isoelectric points of nondenatured polypeptides by two-dimensional electrophoresis and of mol wt by SDS-PAGE on polypeptides on the same sample.

Isolation of glyocalicin and thrombospondin. Glyocalicin was isolated from platelet concentrates that were unsuitable for clinical transfusion, using the methods of Okumura and co-workers¹² and Clemetson and colleagues,¹³ with some modification. The platelets were washed three times with 0.02 mol/L of Tris-HCl (pH 7.6), 0.15 mol/L of NaCl and 1 mmol/L EDTA (TSE) solution, resuspended in 1.0 mol/L of NaCl, 0.02 mol/L of Tris-HCl (pH 7.6) and 1 mmol/L of EDTA, incubated while being stirred at 22 °C for 1 hour, and then centrifuged at 50,000 g for 1 hour at 4 °C. The supernatant was dialyzed at 4 °C against 0.02 mol/L of Tris-HCl (pH 7.6) containing 1 mmol/L of EDTA to reduce the NaCl concentration to 0.15 mol/L and applied to a column (0.9 × 9 cm) of wheat germ agglutinin (WGA) coupled to Sepharose 6-B (Pharmacia, Sweden). Stepwise elution was performed with TSE alone and with TSE containing 4.5 mmol/L of *N*-acetylglucosamine (GlcNAc) or 450 mmol/L of GlcNAc. The 450-mmol/L GlcNAc eluate was dialyzed against 6 mmol/L of potassium phosphate buffer (pH 6.8) with 0.2 mmol/L of EDTA for six changes over 72 hours and then applied to a column (2.5 × 8 cm) of freshly prepared hydroxylapatite. Stepwise elution was performed with 6, 40, and 200 mmol/L of potassium phosphate buffer containing 0.2 mmol/L of EDTA. The fraction eluted with 40 mmol/L of potassium phosphate showed a single band of 130,000 apparent mol wt when analyzed by SDS-PAGE followed by Alcian blue staining. Purified glyocalicin was stored at -20 °C. Thrombospondin was isolated from the supernatants of washed platelets that had been treated with thrombin by the method described previously.¹⁴

Antiserum preparation. Antiplatelet glyocalicin antiserum (raised in rabbits) was obtained from PRP, Inc. (Newton, MA). Antithrombospondin antiserum was prepared in mice. Female BALB/c mice, aged 6 to 10 weeks, were immunized by intraperitoneal (IP) injections with 0.1 mg of purified human platelet thrombospondin and emulsified in complete Freund's adjuvant followed by two booster IP injections (at 3-week intervals) of 50 µg of antigen in TBS/2 mmol/L of CaCl₂ in incomplete Freund's adjuvant. Serum containing antibody was prepared from blood collected 3 weeks after the second booster injection.

Electroblotting and immune staining. Washed platelets were solubilized with SDS and fractionated by SDS-PAGE on 7.5% slab gels.⁷ Fractionated polypeptides were electrophoretically transferred to nitrocellulose paper at 30 V for 20 to 24 hours at 10 °C in pH 8.3 buffer containing 25 mmol/L of Tris, and 192 mmol/L of glycine as described,¹⁵ except that no methanol was used. Nitrocellulose replicas were washed in 0.15 mol/L of NaCl, incubated with phosphate-buffered saline (PBS; pH 7.5) containing 5% bovine serum albumin (PBS-albumin) for 1 hour at 22 °C, then washed with five changes of 0.15 mol/L of NaCl solution over 30 minutes. The protein blots were incubated with either the monospecific antisera against human platelet glyocalicin or thrombospondin, washed, then incubated with horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG (for glyocalicin), or goat anti-mouse IgG (for thrombospondin) (10 µL/10 mL TBS, Cooper Biomedical [Cappel Division], Malvern, PA) for 1 hour at 22 °C. Bound anti-IgGs were detected with 4-chloro-1-naphthol (0.6 mg/mL) and 0.3% hydrogen peroxide in a solution of 20% methanol and 50 mmol/L of Tris-HCl (pH 7.6).

Measurement of ristocetin-induced agglutination. Formalin-fixed platelets were prepared for ristocetin agglutination by a method modified from Coller and co-workers¹⁶ using Gaintner's buffer.¹⁷ A single batch of pooled normal citrate anticoagulated plasma (diluted 1:2) was used as the standard source of factor VIII von Willebrand factor (vWf). The platelet suspension (0.35 mL) was incubated with 0.1 mL of the plasma at 37 °C, and aggregation

was induced by the addition of ristocetin (50 μ L of 1.5 mg/mL). The steepest slope of the agglutination curve was used to assess ristocetin agglutination as described by Weiss.¹⁸

Xylocaine-treatment of platelets. Washed platelets in TBS (1×10^9 /mL) were incubated with xylocaine (40 mmol/L) at 37 °C for 3 hours as described by Collier.¹⁹ Control samples were incubated in the presence of 5 mmol/L of EDTA without xylocaine. After incubation, platelets were washed twice in Tris-buffered saline and prepared for PAT measurement and surface labeling as described previously.

Other methods. Platelet sizing and WBC determinations were done electronically using a Coulter Counter (Model-S). All platelet preparations were 99.9% leukocyte-free. Protein determinations were performed by the method of Lowry and colleagues.²⁰ Individual polypeptides in electrophoresis gels and autoradiograms were estimated by densitometric scanning using a 580-nm filter on a Hoeffer gel densitometer.

RESULTS

The platelets from 68 tumor patients were studied. Of this group, 37 had abnormal platelet antithrombin. The PATs in the abnormal group ranged from 17.0 to 20.5 seconds with an average of 18.6 seconds (SD 0.96). The PATs of the normal group ranged from 21.4 to 29.8 seconds with an average of 25.4 seconds (SD 1.97). The coefficient of variation was 5.2% for the abnormal group and 7.8% for the normal group.

When the polypeptide composition of platelets from the 37 patients with abnormal PAT was analyzed by SDS-PAGE and compared with the protein composition of platelets from 31 patients with normal PAT and three healthy individuals, a marked reduction in a polypeptide of 180,000 apparent mol wt was demonstrated; this difference was evident when gels were stained with either Alcian blue or Coomassie blue (Fig 1A and B). Staining by Alcian blue was found to be more sensitive than that by Coomassie blue, however, in demonstrating alterations of 180,000 mol wt polypeptide. This polypeptide could be readily detected by Alcian blue stain when only 20 to 40 μ g protein from normal platelets was

applied to the gels, whereas 40 to 80 μ g of normal platelet protein was required to detect this polypeptide by Coomassie blue staining. By means of Alcian blue staining, the 180,000-mol wt polypeptide was shown to be decreased or absent in 36 of 37 samples with abnormal PAT and present in the 34 control samples with normal PAT. Purified human platelet thrombospondin, analyzed in parallel with platelet samples, exhibited identical electrophoretic mobility and staining characteristics (under reducing conditions) to this 180,000-mol wt polypeptide (Fig 2). Furthermore, the nitrocellulose replicas of SDS gels of normal platelet proteins showed reaction of this 180,000-mol wt polypeptide with a monospecific antiserum against human platelet thrombospondin; this polypeptide also was decreased or absent in platelets from patients with abnormal PAT (Fig 2). On this basis, the decreased polypeptide in platelets from patients with abnormal PAT was identified as thrombospondin.

Platelet surface glycoproteins from seven of the cancer patients whose platelets showed an abnormal PAT and those from ten individuals with a normal PAT were radiolabeled with ³H and analyzed by two-dimensional isoelectric focusing/SDS-electrophoresis and autoradiography (Fig 3). Under the precise experimental conditions described previously in the Materials and Methods section, platelets from patients with normal PAT showed three major radiolabeled polypeptides. These polypeptides had apparent reduced mol wts of 140,000, 120,000, and 100,000, and relative pIs of 4.5 to 5.2, 5.3 to 5.5, and 5.3 to 5.5, respectively. The polypeptide of ~140,000 mol wt and pI 4.5 to 5.2 was diminished or absent in all seven patients with low PAT. Quantitation of labeled polypeptides by densitometric scanning of autoradiograms showed that the ratio of the densities of the 140,000- to the 120,000-mol wt polypeptide was significantly lower in the abnormal group than in the normal patient group, whereas the densities of the 120,000-mol wt polypeptide were similar in both groups.

Studies were undertaken to examine platelets of the two patient groups with a specific immunochemical probe for

Fig 1. Polypeptide composition of platelets from individuals with normal and abnormal platelet antithrombin test (PAT). Washed platelets were solubilized in 3% sodium dodecyl sulfate (SDS) and fractionated by SDS-polyacrylamide gel electrophoresis (PAGE) on 7.5% polyacrylamide gels under reducing conditions. Gels were stained with Coomassie blue (A) and Alcian blue (B): lane 1, healthy control; lane 2, patient with normal PAT; lanes 3 and 4, patients with abnormal PAT. A polypeptide at 170,000 apparent mol wt is diminished in platelets from patients with abnormal PAT (arrows). For the Alcian blue-stained gels, the tracking dye was run off the leading edge for 30 minutes to improve resolution of high mol wt components. Positions of standard mol wt proteins are as indicated.

Fig 2. Decreased platelet thrombospondin in patients with low platelet antithrombin test (PAT). Washed platelets and purified thrombospondin were fractionated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under reducing conditions and stained with Coomassie blue (lanes 1 through 3). Lane 1, platelets from a patient with abnormal PAT; lane 2, platelets from a patient with normal PAT; lane 3, purified thrombospondin. Nitrocellulose replicas of polyacrylamide gels containing purified thrombospondin (lane 4) and platelets from a healthy control (lane 5), a patient with normal PAT (lane 6), and two patients with abnormal PAT (lanes 6 and 7) were stained by horseradish peroxidase (HRP)-conjugated anti-mouse IgG after incubation with an antiserum monospecific for human platelet thrombospondin. The 180,000-mol wt polypeptide is reduced in lane 1 (arrow) and is absent in lanes 6 and 7. Position of standard mol wt proteins are shown on right.

GPIb—a polyclonal antiserum against purified human platelet glycoprotein. The antiserum (raised in rabbits) reacted with highly purified glycoprotein (mol wt 130,000) and a single, ^3H -labeled polypeptide of apparent reduced mol wt 140,000 when evaluated by staining of nitrocellulose replicas

of SDS gels containing isolated glycoprotein and the fractionated polypeptides of ^3H -labeled, normal platelets (Fig 4).

Platelet GPIb from 14 tumor patients with abnormal PAT and seven normal control subjects were analyzed by the immune replica technique, using the monospecific antiglycoprotein antiserum. There was a reduction in the intensity of staining of the polypeptide corresponding to GPIb in 13 of the 14 patients with abnormal PAT when compared with

Fig 3. ^3H -labeled glycoproteins of platelets from a patient with abnormal platelet antithrombin test (PAT). Platelets from patients with normal (A) and abnormal (B) PAT were fractionated by two-dimensional isoelectric focusing and sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). In autoradiogram B, a protein of 140,000 apparent mol wt and pI of 4.7 is absent but is present in the control platelets shown in A. Mol wt standards are shown on right, and the relative isoelectric points of fractionated polypeptides are shown on the ordinate.

Fig 4. Specificity of anti-human platelet glycoprotein GPIb. Washed normal human platelets were reacted with $^3\text{H}(\text{NaBH}_4)$ after periodate treatment. The ^3H -labeled platelets were extracted with NP-40 and then fractionated by sodium dodecyl sulfate (SDS)-electrophoresis on a 7.5% polyacrylamide resolving gel under reducing conditions. Platelet extract: stained with Coomassie blue (lane 1), Alcian blue (lane 2), after fluorography to detect radiolabeled surface glycoproteins (lane 3), and in a nitrocellulose replica after reaction with the anti-human platelet glycoprotein antiserum, which stained a polypeptide of 140,000 mol wt (Δ) (lane 5). Lanes 4 and 6 represent the corresponding reactions of purified human platelet glycoprotein (3 μg) with Alcian blue and with the antiglycoprotein antiserum, respectively. Positions of mol wt standards are shown on right.

platelets from seven normal control subjects (Fig 5, lanes 3 through 6). Degradation products of GPIb were visible (indicated by low mol wt polypeptide that reacted with the antiglycocalicin antiserum) in four patients with abnormal PAT (Fig 5, lanes 3 and 4). The apparent mol wt for two degradation polypeptides shown by the two diffuse bands in Fig 5, lane 4 were 120,000 and 105,000.

Ristocetin-induced platelet agglutination was significantly lower in patients with abnormal PAT. For the group with normal PAT, the average steepest slope of agglutination was 1.25 ± 0.6 ($n = 28$). For the group with abnormal PAT, the average slope was 0.37 ± 0.34 ($n = 26$) (Fig 6). The difference between those two groups was statistically significant ($P < .001$).

Attempts to reproduce the PAT defect in normal platelets in vitro were made by exposing platelets to xylocaine, which is known to stimulate proteolysis of GPIb.¹⁹ In two experiments, xylocaine treatment produced a decrease of antithrombin activity in platelets. The PAT was reduced from 31 seconds before treatment to 21 seconds after treatment in one experiment and from 23 seconds to 18 seconds in another. The effect of the xylocaine treatment could be seen on the two-dimensional PAGE and autoradiogram of ³H-labeled platelets as an absence of a protein of 140,000 mol wt at pI of 4.5 to 5.2 (Fig 7).

DISCUSSION

Platelet antithrombin activity denotes the ability of platelets to neutralize the clotting activity of thrombin.¹ Previous reports^{21,22} have implicated GPIb as the protein responsible

Fig 5. Alterations of the platelet GPIb in patients with abnormal platelet antithrombin test (PAT). Platelets (40 μ g) and purified glycocalicin (2 μ g) and thrombospondin (2 μ g) were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and then electrophoretically transferred to the nitrocellulose paper. The replicas were stained by horseradish peroxidase (HRP)-conjugated anti-rabbit IgG after incubation with a monospecific antiserum against purified human platelet glycocalicin. Lane 1, purified glycocalicin; lane 2, purified thrombospondin; lanes 3 through 5, patients with abnormal PAT; lane 6, healthy control subject. The estimated mol wt for glycocalicin is 127,000 (lane 1); for GPIb (lanes 5 and 6), 140,000, and for the two degradation polypeptides in lane 4, 120,000 and 105,000. Position of standard mol wt proteins is shown on right.

Fig 6. Ristocetin-induced agglutination of platelets from two patients with normal platelet antithrombin test (PAT) (curves A and B) and two patients with abnormal PAT (curves C and D). Results were from a typical experiment using identical concentrations of pooled plasma and ristocetin for all samples tested.

for antithrombin activity. Glycocalicin, a proteolytic product of GPIb, has been shown by other investigators to prolong the thrombin clotting time and inhibit competitively ristocetin-induced platelet aggregation^{22,23}; it has been implicated as the site of thrombin and vWF binding within the GPIb molecule.¹² Recently, Takamatsu and colleagues,²⁴ by chemical cross-linking studies, demonstrated one major thrombin receptor on the platelet surface and showed that the receptor binding is blocked by antiglycocalicin antibody.

In this study, a platelet glycoprotein interacting with antiglycocalicin antibody and having a mol wt of 140,000 and a pI of 4.5 to 5.2 was decreased in patients with an abnormal PAT. The electrophoretic pattern (as described previously), which showed characteristics similar to those of

Fig 7. Surface-labeled glycoproteins of platelets after treatment with xylocaine (4 mmol/L). The glycoproteins of xylocaine-treated platelets were ³H-labeled and fractionated by two-dimensional isoelectric focusing sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Panel B shows the absence of a protein of apparent mol wt of 140,000 and a pI of 4.5 to 5.2 that is present in the nontreated control platelets (A). Mol wt standards are shown at right, and the relative isoelectric points are shown on the ordinate.

GPIb as reported by others,^{25,26} along with positive staining of the immunoblot by antglycocalicin antibody, suggests that this protein is GPIb.

The mechanism that produces the GPIb defect as demonstrated in this study is not known. It may be due to quantitative reduction of GPIb on the platelet surface or to a structural alteration of the molecule so that it no longer reacts to monospecific antibody against glycocalicin. GPIb is a prominent surface membrane glycoprotein, rich in sialic acid content and, as such, can be readily labeled with tritiated borohydride after generation of reactive carbonyl groups with sodium periodate. When tritiated platelets were analyzed by two-dimensional PAGE, a deficiency of GPIb also was demonstrated in platelets from patients with low PAT. The latter results may reflect less glycosylation of GPIb. Disialation by neuraminidase treatment, however, caused a retardation of electrophoretic mobility of GPIb in SDS-PAGE.²⁷ Results from the present surface labeling and immunoblotting studies failed to show such effects.

Ristocetin-mediated binding of vWF to normal platelets is dependent on the integrity of GPIb.²⁸ Antibodies prepared against GPIb have prevented platelet agglutination in response to ristocetin.²⁹ Platelets of patients with Bernard-Soulier syndrome who are deficient in GPIb also fail to respond to ristocetin and bind less thrombin than do normal patients.³⁰

Decreased concentrations of GPIb have been described in thrombocythemia by other investigators.^{31,32} This is consistent with the previously reported decreases in PAT in that disease.⁴ Additional supporting evidence that GPIb is the platelet protein accounting for most platelet antithrombin activity comes from experiments dealing with exposure of normal platelets to xylocaine. This procedure causes cleavage of glycocalicin from GPIb (Fig 7) as well as diminished platelet antithrombin activity.

Both thrombin and plasmin are known to degrade GPIb.^{23,33} Therefore, the depletion of GPIb from platelets may be the result of the generation of circulating proteolytic enzymes in cancer patients. No direct evidence confirms proteolysis of GPIb of platelets with reduced PAT; however, the demonstration of low mol wt fragments of GPIb is consistent with proteolytic degradation of this surface glycoprotein. Release of calcium-dependent protease (CDP) from platelets can also cause depletion of GPIb.^{28,34} Because all

platelet samples were prepared and lysed in the presence of EDTA and iodoacetamide, which are inhibitors of CDP,³⁵ it is doubtful that depletion of GPIb from platelets is an *in vitro* phenomenon caused by the release of CDP during washing and solubilization of platelets.

Diminished platelet sialic acid content has previously been associated with malignancy,³⁶ as has increased plasma sialic acid.³⁷ The latter has been correlated with the extent of tumor mass.³² Because glycocalicin is found to circulate in normal plasma,³⁸ it would be of interest to determine if any portion of the increased plasma sialic acid is accounted for by glycocalicin.

Decreased amounts of a second protein of apparent mol wt of 180,000 were also found in platelets of patients with low PAT. This protein was identified as thrombospondin on the basis of a comparison of its electrophoretic, immunologic, and staining properties with those of purified thrombospondin. Thrombospondin is an α -granular protein, composed of three apparently identical chains. It is released and expressed on the platelet surface in response to thrombin stimulation.¹⁵ Thrombospondin is deficient in platelets from patients with gray platelet syndrome³⁹ as well as from patients with thrombocythemia.^{40,41} Thrombospondin has been postulated to have multiple functions. The presence of thrombospondin on the platelet membrane was found to increase fibrinogen binding.⁴² Because surface-bound fibrinogen accounts for 25% of the platelet antithrombin activity,³ the absence of thrombospondin could indirectly account for the decrease in PAT.

It is unknown at this time whether the similar protein changes account for platelet antithrombin defect in nonmalignant disease.⁴ In addition, the unequivocal proof of a cause-effect relationship between platelet antithrombin deficiency and the depletion of GPIb and thrombospondin is still lacking. Nevertheless, this study provides the first evidence to link the antithrombin defect and alterations of glycoproteins in platelets from patients with malignant disease.

Interrelationship Between Mitosis and Endomitosis in Cultures of Human Megakaryocyte Progenitor Cells

By Moises Arriaga, Karen South, Janet Lee Cohen, and Eric M. Mazur

Sera from dogs rendered aplastic by total-body irradiation stimulate human bone marrow megakaryocyte progenitors to form megakaryocyte colonies in plasma clot cultures. In this investigation, we evaluated the effects of varying concentrations of such sera on both the mitotic and endomitotic phases of human megakaryocyte development in vitro. When low concentrations of aplastic canine sera (2.5% to 5.0% [vol/vol]) were added to cultures of human peripheral blood mononuclear cells in place of normal AB serum, megakaryocyte colony formation was augmented fivefold, cell numbers per colony increased approximately 2.5-fold, and the geometric mean megakaryocyte ploidy almost doubled. Further increasing the aplastic canine serum concentration from 10% to 30% (vol/vol) stimulated no additional colony formation. However, there was a further augmentation of cell numbers per colony associated with a progressive decrease in the mean megakaryocyte ploidy. Megakaryocyte cultures were harvested after 7, 12, 15, and 19 days of incubation, and these demonstrated that the lower mean ploidy values found at

the higher concentrations of aplastic canine serum did not result from delayed endoreduplication. At all aplastic serum concentrations evaluated, there existed a strong correlation between nuclear ploidy and cell diameter. We conclude that both the mitotic and endomitotic events in human megakaryocytopoiesis may be influenced by a factor or factors present in aplastic canine serum. At lower in vitro concentrations, such sera stimulate both mitosis and endomitosis, which promotes the development of megakaryocyte colonies composed of larger cells with a higher mean ploidy. With increasing aplastic serum concentrations, colony formation plateaus and mitosis is favored over endomitosis. This results in colonies composed of more numerous but smaller megakaryocytes with a lower mean ploidy. Our data suggest that the size and extent of polyploidization that can be achieved by a developing megakaryocyte may be influenced by the mitotic prior history of its immediate precursor cell.

© 1987 by Grune & Stratton, Inc.

THE DEVELOPMENT of a clonogenic in vitro culture system for the human megakaryocyte progenitor cell (CFU-Meg) has led to the identification of a serum substance, megakaryocyte colony-stimulating factor (Meg-CSF), that stimulates mitosis and the early development of the CFU-Meg.¹⁻³ This factor promotes in vitro megakaryocyte colony formation from normal human CFU-Meg and increases the number of megakaryocytes developing in each colony.¹ Meg-CSF has been detected in sera obtained from patients with aplastic anemia,^{1,2} amegakaryocytic thrombocytopenia⁴ and from patients who are at a hematologic nadir following chemotherapy.⁵ Because Meg-CSF is not detected in sera from patients with consumptive thrombocytopenia, we have postulated that its elaboration is a response to the depletion of bone marrow megakaryocytes or megakaryocyte progenitor cells.²

We recently described and partially characterized an analogous Meg-CSF in the sera of dogs rendered aplastic by total-body irradiation.⁶ Canine is as active as human Meg-

CSF in promoting mitotic expansion and the early development of human megakaryocyte progenitors. However, resultant platelet production is determined not only by the number of cell divisions occurring during CFU-Meg development. The mitotic amplification of each megakaryocyte progenitor cell is generally followed by a variable number of endomitotic nuclear replications. This results in a population of mature megakaryocytes that is heterogeneous with respect to ploidy. Because platelet production per megakaryocyte increases with ploidy, the total number of platelets produced from the development of each megakaryocyte progenitor is determined predominantly by the extents to which mitosis and endomitosis occur.⁷

The regulatory determinants of megakaryocyte polyploidization are not well understood. In this investigation, we have explored the hypothesis that mitotic events occurring during early megakaryocytopoiesis may interact with subsequent megakaryocyte polyploidization. We have used a plasma clot culture system for human peripheral blood CFU-Meg in which varying mitotic stimulation was provided by different concentrations of Meg-CSF containing aplastic canine sera. Techniques were developed for the concurrent in situ immunohistochemical identification, enumeration, and DNA quantitation of cultured megakaryocytes. Aplastic canine sera induced significant concentration-dependent effects on both the mitotic and endomitotic phases of human megakaryocyte development in vitro. Our data suggest that these two processes may be linked.

MATERIALS AND METHODS

Human subjects. Peripheral blood for CFU-Meg cultures and normal AB sera was obtained by routine venipuncture from consenting healthy adult donors who provided written informed consent.

Canine sera. Aplastic canine sera were prepared as previously described.⁶ The lot of serum used in this investigation was harvested from an animal whose platelet count was 4,000/ μ L at the time of sacrifice.

Plasma clot megakaryocyte cultures. Human peripheral blood was diluted 1:1 with α -medium minus nucleosides (GIBCO, Grand Island, NY) containing preservative-free heparin at 20 U/mL. Mononuclear cells were isolated by Ficoll 400–sodium diatrizoate (LSM, Litton Bionetics, Kensington, MD) density centrifugation. The cells were suspended in α -medium containing 20% AB serum, and the plastic-adherent cells were removed by a one-hour incubation at 37 °C in 100-mm polystyrene tissue culture dishes (Corning Glass Works, Corning, NY). Plasma clot megakaryocyte cultures were established as previously described.^{1,2,8} Plastic-adherent cell-depleted mononuclear cells were cultured at 10^6 cells/mL in 1-mL volumes in 35-mm Petri dishes. Aplastic canine serum containing Meg-CSF was added to the cultures at time 0 in concentrations ranging from 0% to 30% (vol/vol), replacing equal volumes of normal AB sera in the cultures. A single lot of aplastic canine serum and lots of equivalent normal human AB sera were used in all experiments. Culture dishes were incubated for 12 days (unless otherwise indicated) at 37 °C in a 100% humidified atmosphere of 5% CO₂ in air using a NAPCO 5200 water-jacketed incubator (National Appliance Co, Portland, OR). Harvesting was performed by fixation in situ with methanol:acetone (1:1) for 20 minutes, sequential washing with 0.01 M/L phosphate-buffered saline (PBS), pH 7.2, and distilled water, and then air drying. The plasma clots were stored frozen at –20 °C until immunofluorescent staining was performed.

Immunofluorescent staining and scoring of cultures. Rabbit antiserum to platelet glycoproteins (PGP) was prepared and its specificity demonstrated as previously reported.^{1,2,8} Megakaryocyte colonies were labeled immunofluorescently by sequential incubations with PGP antiserum diluted 1/200 in PBS and rhodamine-conjugated goat antirabbit IgG (IgG fraction) diluted 1/60 in PBS (Cappel Laboratories, Cochranville, PA). A rhodamine rather than fluorescein conjugate was used for the second label because its optical signal was stable to the acid hydrolysis required for DNA quantitation.

After air-drying, the plasma clot megakaryocyte cultures were scored in situ. The 35-mm Petri dishes were inverted, the base areas completely scanned, and rhodamine-positive colonies enumerated with a fluorescent light microscope at 100 $\times$ (Olympus BH-2 microscope with a vertical fluorescent illuminator, Olympus Corp, New York). A megakaryocyte colony was defined as a cluster of three or more intensely rhodamine-positive cells. All experiments were performed in duplicate.

DNA quantitation. Staining for quantitative DNA determination was performed using a modified Feulgen technique adapted from Ruch.⁹ The compound 2,5-bis-(4-aminophenyl)-(1') = 1,3,4 oxadiazole (I), (BAO; Fluka Chemical Corp, Happaug, NY) was chosen as the DNA fluorochrome because its relative stability to UV irradiation resulted in a minimal influence of the time of light exposure on DNA measurements.⁹ BAO is comparable to Auramine O in its specificity for DNA⁹ and has been recommended by Paulus et al for the Feulgen staining of human bone marrow megakaryocytes.¹⁰ In our laboratory, Feulgen/BAO staining is 96% DNA specific based upon the reduction in the nuclear fluorescent signal induced by exposure to deoxyribonuclease I (Sigma Chemical Co, St Louis) prior to staining. For this determination, human peripheral blood smears were fixed in methanol:acetone (1:1), and the test smears were preincubated in DNAase I at 0.5 mg/mL in 0.03 M/L magnesium sulfate, pH 6.0. Control and test smears were Feulgen stained with BAO as will be described and the mean nuclear fluorescent signals determined from the nuclei of polymorphonuclear leukocytes. Following DNA digestion, the mean nuclear fluorescence was reduced from 49.2 to 2.0 (arbitrary units).

The fixed, PGP-rhodamine-labeled plasma clot cultures were rehydrated with distilled water, and then the DNA was hydrolyzed

in 4 N HCl at 37 °C for 20 minutes. Hydrolysis was terminated by aspirating the HCl and flooding the culture dishes with distilled water at room temperature. Nuclear DNA was stained using freshly prepared BAO reagent (20 parts 0.01% BAO in distilled water (wt/vol) to two parts 1 N HCl to one part 10% sodium metabisulfite [wt/vol]). One milliliter of BAO reagent was layered on each 35-mm Petri dish, and the cultures were gently agitated for 30 minutes at room temperature in a 100% humidified chamber. BAO staining was followed by three two-minute washes with sulfite water (18 parts distilled water, one part 1 N HCl, one part 10% sodium metabisulfite [wt/vol]), one ten-minute wash with distilled water, and dehydration with 70% ethanol. The culture dishes were air-dried, the plastic sides removed, and circular coverslips mounted with glycerol.

Megakaryocyte DNA quantitation was performed using a Leitz Laborlux 12 microscope equipped with an adjustable measuring diaphragm, an MPV compact microscope photometer, and interchangeable filter cubes (Ernst Leitz, Wetzlar, W Germany) interfaced with an Epson HX-20 computer (Epson America, Inc, Torrance, CA). The measuring diaphragm was located in the emitted light pathway, and adjustment of its aperture did not influence incident illumination.⁹ Green-band "Cube N2" (excitation filter BP 530 to 560 nm and barrier filter LP 580 nm) was used for the identification and enumeration of the PGP-rhodamine-labeled megakaryocytes, and wide-band UV "Cube A" (excitation filter BP 340 to 380 nm and barrier filter LP 430 nm) was used to measure BAO fluorescence.

At a magnification of 100 $\times$ the megakaryocyte colonies were identified in situ in the plasma clot by rhodamine fluorescence, and single megakaryocytes were randomly selected for DNA quantitation. When the total number of megakaryocytes in a culture plate exceeded 200, representative sampling was assured by (1) measuring nuclear DNA in equal numbers of cells from both halves of that culture plate and (2) analyzing no more than three to four arbitrarily selected megakaryocytes in each colony. Within the colonies, cells were chosen based upon the order in which they were encountered while scanning using green incident light at 400 $\times$. This sampling algorithm was validated in ten representative instances by comparing repeat ploidy distributions determined each from 100 randomly chosen megakaryocytes in the same culture plate. Ploidy distributions did not differ significantly between paired determinations, and duplicate mean ploidy values had coefficients of variation averaging $8.6\% \pm 5.9\%$ ($\pm$ SD).

Megakaryocyte DNA was measured using UV light excitation. At a magnification of 400 $\times$ the nucleus of each megakaryocyte was isolated using the adjustable measuring diaphragm, and its BAO fluorescent signal was quantitated photometrically. The background readings were taken in the same high-power field as each megakaryocyte using the same diaphragmatic aperture. The net megakaryocyte DNA emission signal (M_i) was calculated as the difference of the two values. Readings of diploid-cell DNA fluorescence, D_j , (corrected for the background) were obtained throughout the culture specimen in a diploid cell:megakaryocyte ratio of approximately 1:2. When a culture dish was completely scored, the relative DNA content per cell for each of the megakaryocytes was determined using the following relationship:

$$\text{Megakaryocyte DNA content (i)} = \frac{M_i}{\left[\sum_{j=1}^n D_j \right]} \times 2$$

where n was the number of diploid cells evaluated in that culture dish. Megakaryocytes were assigned to the ploidy level of the nearest modal value of DNA content according to the algorithm of Paulus et al.¹⁰ The measurements, calculations, and ploidy assignment were

performed using an on-line Epson HX-20 computer that permitted the evaluation of 75 to 100 cells per hour. Each high-power field received a total of no more than 30 seconds of UV light exposure.

The mean megakaryocyte ploidy was calculated from the following equation:

$$\text{Mean megakaryocyte ploidy} = \text{anti-log}_2 \left[\frac{\sum_{p=2}^{64} \log_2(p) \times n_p}{n} \right]$$

where n_p is the number of megakaryocytes in ploidy class p ($p = 2, 4, 8, \dots, 64$) and n is the combined number of megakaryocytes in all ploidy classes. The geometric mean megakaryocyte ploidy is a more accurate representation of the mean ploidy than the linear average used in some studies^{11,12} because the linear average disproportionately weights the contribution of higher-ploidy megakaryocytes.

Megakaryocyte size. Megakaryocyte diameters were determined at 400 $\times$ magnification using a calibrated eyepiece micrometer.

Statistical analyses. Megakaryocyte ploidy distributions were compared by Pearson's χ^2 test of independence of distributions.¹³ Other comparisons were made using Student's t test or linear regression analyses.

RESULTS

Similar to what we have reported previously,⁸ low-level megakaryocyte colony formation from peripheral blood mononuclear cells was observed in unstimulated cultures containing only normal human AB serum. In such cultures 10.4 ± 3.8 (mean $\pm$ SEM) megakaryocyte colonies were grown from 10^6 mononuclear cells (Fig 1). The addition of aplastic canine serum stimulated up to a fivefold increase in colony formation (Fig 1). The megakaryocyte colony numbers reached a maximum of 54.4 ± 11.2 (mean $\pm$ SEM) at an aplastic canine serum concentration in a culture of 2.5% (vol/vol). With further increases in the aplastic canine serum

Fig 1. Effects of the concentration of aplastic canine serum on megakaryocyte colony numbers (●) and the number of megakaryocytes per colony (▲) after 12 days in culture. Each point represents the mean $\pm$ SEM of three (cells/colony) or four (colony numbers) separate experiments where assays were performed in duplicate. The data on megakaryocytes per colony incorporated observations from a total of 866 colonies whose distribution by size is displayed in Table 1. Megakaryocyte colony numbers were significantly increased ($P < .05$ by Student's t test) above the control (0%) at all aplastic canine serum concentrations evaluated except 1%. Colony numbers were maximal at 2.5% aplastic canine serum, and the numbers observed between 5% and 30% did not differ significantly from the peak value. The mean number of megakaryocytes per colony was linearly related to the concentration of aplastic canine serum ($r = .952$, $P < .001$).

concentration, the megakaryocyte colony formation plateaued (Fig 1).

Aplastic canine serum also enhanced the number of cells developing in each megakaryocyte colony, but there was no plateau in the dose-response effect. The mean number of megakaryocytes in each colony increased almost monotonically throughout the entire concentration range of aplastic canine serum evaluated (Fig 1). Cells per colony rose from 5.8 ± 0.5 (mean $\pm$ SEM) in cultures containing only normal AB serum to 46.1 ± 11.4 (mean $\pm$ SEM) at the maximum aplastic canine serum concentration of 30% (vol/vol). The distribution of megakaryocyte colony size as a function of aplastic canine serum concentration is presented in Table 1. With increasing aplastic canine serum concentrations, there was a continuous upward shift in the modal colony size. In addition, the maximal colony sizes progressively increased, which reflected the stimulation of up to four mitotic generations beyond that observed in unstimulated cultures.

The same cultures used to evaluate colony numbers and size were stained with BAO for DNA quantitation. Because individual megakaryocyte colonies grown in plasma clot cultures are typically dispersed,^{1,8} overlapping of constituent cells was not a significant problem in performing such measurements. Illustrated in Fig 2 is a representative megakaryocyte colony in which both megakaryocyte cytoplasm is labeled immunochemically with anti-PGP/rhodamine and nuclei are stained with BAO. In Fig 2B there are additional cells whose nuclei stain with BAO but do not label with the anti-PGP/rhodamine. These cells, consisting predominantly of macrophages and lymphocytes, served as the diploid standards from which megakaryocyte ploidy was calculated. The coefficient of variation for the diploid cell DNA fluorescent signals averaged 32.5%, and the background fluorescence constituted approximately 30% of the total 2N nuclear measurements.

The effect of increasing concentrations of aplastic canine serum on cultured megakaryocyte mean ploidy was biphasic (Fig 3). Between aplastic serum concentrations of 0% and 2.5% (vol/vol), a significant enhancement of ploidy was observed, with the mean values rising from 6.97N at 0% to 12.66N at 2.5% ($P < .01$ by Pearson's χ^2).¹³ The peak megakaryocyte ploidy was observed at the same aplastic serum concentration as that at which colony formation attained its maximum (Fig 1). The mean ploidy decreased with further increases in the aplastic serum concentration and reached a minimum of 4.98N at 30% aplastic serum. The enhancement of megakaryocyte ploidy by aplastic serum at concentrations of 2.5% to 10% was a result of a shift in the distribution of cells from the 4N and 8N to the 16N and 32N ploidy classes. At aplastic canine serum concentrations of 15% to 30% in culture, a decreasing mean ploidy resulted from increases in 2N and 4N cells at the expense of 16N, 32N, and 64N cells (Table 2).

The kinetic aspects of megakaryocyte polyploidization in culture were determined to evaluate the impact of culture duration on ploidy. Megakaryocyte cultures containing 0%, 2.5%, and 20% aplastic canine serum were harvested serially following 7, 12, 15, and 19 days of incubation (Fig 4). The peak mean ploidy values were observed on days 12 to 15 of

Table 1. Distribution of Megakaryocyte Colony Size as a Function of the Concentration of Aplastic Canine Serum in Culture

2.5	143	29.4	28.0	26.6	14.7	1.4	0	0
5	140	12.1	37.1	34.3	13.6	2.9	0	0
10	147	8.2	27.2	42.9	17.7	4.1	0	0
15	107	7.5	15.0	32.7	28.0	9.4	7.5	0
20	155	8.4	24.5	32.3	23.9	10.3	0.7	0
30	90	7.8	13.3	25.6	25.6	11.1	10.0	6.7

The data are derived from three experiments and a total of 866 colonies. The arithmetic means and statistical analysis of these data are presented in Fig 1.

*The concentration (vol/vol) of aplastic canine serum in culture replacing an equal volume of normal AB serum.

†The interval range for colony size is calculated as $2^{(n-0.5)}$ to $2^{(n+0.5)}$ ($n = 2, 3, \dots, 8$), where n represents successive mitotic generations (doublings). The values are given as the percentage of the total colonies.

culture regardless of the concentration of aplastic serum used. The biphasic relationship of mean ploidy with aplastic serum concentration was seen as early as seven days and persisted through day 15 of culture. By day 19, many of the megakaryocyte colonies had degenerated, and the mean ploidies became equivalent at all serum concentrations tested. In the cultures containing 20% aplastic canine serum, there was no increase in ploidy beyond 12 days of culture. Thus, the lower mean ploidy seen in day 12 cultures (Fig 3) was not simply the result of delayed endoreduplication.

Because megakaryocyte size is known to vary with ploidy *in vivo*,^{7,14} this relationship was analyzed in the *in vitro* culture system. At all aplastic canine serum concentrations evaluated, the megakaryocyte size varied significantly with $\log_2$ (ploidy). The slopes and intercepts of the regression lines relating these two parameters did not vary significantly among the different aplastic serum concentrations (data not shown). Therefore, megakaryocyte size *v* ploidy data from all aplastic canine serum concentrations were consolidated and are presented in Fig 5.

DISCUSSION

The production of platelets from the committed megakaryocyte progenitor cell or CFU-Meg is complex, requiring

nearly sequential mitosis, endomitosis, and cytoplasmic maturation.⁷ However, the physiological regulatory control systems governing these processes are for the most part poorly understood. We have recently reported that sera from patients with bone marrow megakaryocyte aplasia^{1,2,4} and from dogs with irradiation-induced aplasia⁶ contain a substance, Meg-CSF, that stimulates mitosis and the early development of human bone marrow CFU-Meg. Meg-CSF manifests this effect in culture by augmenting both the number of megakaryocyte colonies grown and the number of component cells developing in each colony.^{1,3}

In this report, we establish that Meg-CSF containing aplastic canine serum has qualitatively similar effects on human peripheral blood CFU-Meg progenitors. We have also been able to demonstrate an interaction between varying mitotic stimulation of early megakaryocytopoiesis by aplastic serum and the degree of megakaryocyte polyploidization achieved in culture.

We observed an unexpected biphasic effect of increasing concentrations of aplastic canine serum on *in vitro* megakaryocytopoiesis. Compared with control cultures containing only normal AB serum, low culture concentrations of aplastic canine serum (2.5% to 5.0% [vol/vol]) augmented megakaryocyte colony formation fivefold, increased cell numbers

Fig 2. Representative megakaryocyte colony double labeled with PGP antiserum/rhodamine (A, green incident light) and BAO (B, UV incident light) that was cultured from human peripheral blood mononuclear cells in the presence of aplastic canine serum (original magnification $\times 100$).

Fig 3. Effect of the concentration of aplastic canine serum in culture on the geometric mean ploidy of megakaryocytes cultured from human peripheral blood mononuclear cells. Data from three experiments were combined and include ploidy determinations on a total of 2,078 megakaryocytes. A mean of 260 cells was evaluated at each point (Table 2). Ploidy distributions at adjacent aplastic canine serum concentrations differ significantly in the following instances: 1.0% v 2.5%, 10% v 15%, and 20% v 30% ($P < .01$ by Pearson's χ^2); and 5% v 10% ($.01 < P < .02$).

per colony approximately 2.5-fold, and almost doubled the mean ploidy. Further increasing the aplastic serum concentration from 10% to 30% (vol/vol) stimulated no additional colony formation. However, there was a further augmentation of cell numbers per colony associated with a progressive decrease in the mean megakaryocyte ploidy. Thus, in those cultures containing the higher concentrations of aplastic canine serum, an inverse relationship was present between mitotic amplification of the megakaryocyte progenitor (as manifested by cell numbers per colony) and the extent of megakaryocyte endoreduplication.

Our results appear to conflict with similar studies in mice reported by Chatelain and Burstein.¹⁵ They found no effect of increasing concentrations of pokeweed mitogen-stimulated spleen conditioned medium on cultured murine megakaryocyte ploidy, despite slight augmentations in colony numbers and size. The effects that we observed using aplastic canine serum may therefore be dependent upon this specific

Fig 4. Effect of culture duration on the geometric mean ploidy of megakaryocytes cultured from human peripheral blood mononuclear cells. The cultures contained aplastic canine serum concentrations of 0% (●), 2.5% (■), and 20% (▲). Data are derived from two experiments with ploidy determinations on 3,163 megakaryocytes.

source of Meg-CSF, result from the higher cell plating densities we used, or reflect the substantially greater changes in colony size seen in our studies.

That megakaryocyte development from its progenitor may be characterized by a reciprocal relationship between mitosis and endomitosis has been demonstrated previously by other investigators.^{11,15-17} However, these earlier studies analyzed differences among individual murine megakaryocyte colonies that were generally cultured under conditions providing maximal growth stimulation. It was found that colonies with larger numbers of cells had lower mean ploidy values. Cell number and mean ploidy differences among colonies were attributed to an intrinsic heterogeneity of the CFU-Meg progenitor cell population.

Our studies indicate that, although CFU-Meg heterogeneity may exist, mitosis and endomitosis can be further influenced in culture by a factor or factors present in aplastic canine serum. Because colony numbers plateau at aplastic serum concentrations of 2.5% and above, it is probable that the higher aplastic serum concentrations affect a fixed population of megakaryocyte progenitors rather than selectively recruit different progenitor classes. Therefore, the

Table 2. Ploidy Distributions of Progenitor Cell—Derived Megakaryocytes Cultured With Varying Concentrations of Aplastic Canine Serum

Fig 5. Relationship between diameter and ploidy class for megakaryocytes cultured from human peripheral blood mononuclear cells. Data are derived from 715 cells and are presented as the mean $\pm$ SD. A significant linear correlation was observed ($r = .665$, $P < .001$).

inverse relationship between mitosis and endomitosis that was previously attributed exclusively to progenitor cell heterogeneity likely also characterizes megakaryocytopoiesis in general. It is speculative whether this relationship is physiologically adaptive and operates *in vivo*. However, one may hypothesize that in conditions of severe megakaryocytic hypoplasia with accompanying thrombocytopenia, mitotic amplification of existing megakaryocyte precursors, even at the expense of endomitosis, may most effectively restore platelet production. This hypothesis is supported by a recent report by Tanum who demonstrated that the resumption of platelet synthesis in rats receiving a sublethal dose of thiopeta is temporally associated with the exclusive appearance of low-ploidy megakaryocytes in the bone marrow.¹⁸

Although Meg-CSF is known to be present in aplastic canine sera, this investigation does not distinguish between its effects and those of other regulators potentially present in such sera. The existence of additional regulators that influence megakaryocyte endoreduplication and cytoplasmic maturation have been postulated by several investigators.¹⁹⁻²² However, even if these exist, our data indicate that their influence may be limited by the mitotic history of the cells upon which they act. Another hypothesis consistent with our data is that Meg-CSF alone controls both the mitotic and endomitotic phases of megakaryocytopoiesis, with differential effects depending upon the intensity of Meg-CSF stimulation.

The normal AB sera used in our experiments may also have included factors capable of affecting megakaryocyte development *in vitro*. Several investigators have suggested that normal sera contain platelet-derived inhibitors of megakaryocyte colony formation.^{23,24} However, it is unlikely that such inhibitors, if present, substantially influenced our experimental results because both peak megakaryocyte colony formation and maximal nuclear polyploidization were achieved at a concentration ratio of aplastic canine to normal AB serum of less than 0.10. It is also improbable that the aplastic canine serum contained substantial quantities of platelet-derived inhibitors, given the low platelet count at the time of its preparation. We have recently established that the megakaryocyte colony-stimulating activity manifested by aplastic canine sera results from the presence of a positive regulatory protein rather than from the absence of inhibitors found in normal sera.⁶

By examining the polyploidization of human megakaryocyte progenitors in culture, our studies represent an extension of the previously published murine *in vitro* studies.^{11,12,15-17,22} Our use of immunochemical labeling of cultured human megakaryocyte colonies for identification with concurrent

Feulgen-BAO staining *in situ* for DNA quantitation is analogous to those murine studies in which megakaryocyte colonies were double labeled *in situ* for acetylcholinesterase and DNA.¹⁵⁻¹⁷ Such approaches provide unequivocal identification of all megakaryocytes present within a culture (including low-ploidy cells) and eliminate both the biases inherent in morphological identification using inverted microscopy and the cell losses that accompany colony transfer to glass slides for DNA analysis. The use of Feulgen-BAO staining coupled with microfluorometry for the determination of the cellular DNA content represents a technically straightforward and accurate approach to DNA quantitation, one that does not require the expensive equipment necessary for scanning microdensitometry. Furthermore, distributional errors, excessive signal-to-noise ratio, and light scatter are minimized or eliminated.^{10,25} Imprecision resulting from photodecomposition of the DNA fluorochrome is minimized by using BAO for which the fluorescent signal is relatively stable to the UV incident light used for excitation.⁹

This investigation also examined the relationship between cultured megakaryocyte ploidy and diameter. The positive correlation we observed (Fig 5) is similar to that previously described for megakaryocytes harvested directly from bone marrow.¹⁴ Our data defined a smaller megakaryocyte diameter for each ploidy class than that described by these other investigators. Possible explanations for this discrepancy include cell shrinkage due to fixation or the failure of the cultured megakaryocytes to achieve full cytoplasmic maturation *in vitro*. Nevertheless, this positive correlation demonstrates that the link between ploidy and cytoplasmic development previously found to exist *in vivo* is maintained during *in vitro* megakaryocyte development.

The availability of megakaryocyte progenitor cell culture systems in which one can concurrently quantify colony formation, cell numbers per colony, and endoreduplication provides new opportunities for analyses of megakaryocytopoietic regulation. Our data indicating that the mitotic history of a megakaryocyte precursor may influence its endoreduplicative potential serve to emphasize both the complexity of this regulatory system and the potential utility of the methods described in this investigation.

ACKNOWLEDGMENT

We gratefully acknowledge the gift of the Leitz microscope, MPV compact photometer, and Epson HX-20 computer from the Masonic Grant Lodge Charities of Rhode Island. The word processing assistance of Valerie Krasko, Kathy Wahl, and Sandra Kopel is greatly appreciated.

The Role of Glutathione Reductase in Maintaining Human Granulocyte Function and Sensitivity to Exogenous H_2O_2

By Harvey J. Cohen, Elizabeth H. Tape, John Novak, Margaret E. Chovaniec, Patricia Liegey, and John C. Whitin

Human granulocytes (polymorphonuclear leukocytes, PMN) produce H_2O_2 and other reactive oxygen species while undergoing phagocytosis. To examine the role of the glutathione cycle in metabolizing H_2O_2 , we incubated PMN with 1,3-bis(2-chloroethyl) nitrosourea (BCNU). Incubation of PMN with BCNU results in a dose-dependent inhibition of PMN glutathione reductase (GRED), with 50% inhibition occurring at approximately 2 $\mu\text{g}/\text{mL}$ BCNU. PMN hexose monophosphate shunt activity stimulated with an exogenous H_2O_2 -generating system was inhibited only when the GRED activity was reduced to less than 30% of control. BCNU-treated cells contained lower levels of reduced sulfhydryls and reduced glutathione, which decreased even more in the presence of an exogenous H_2O_2 -generating system. The effect of BCNU and exogenous H_2O_2 on various aspects of phagocytosis were examined. Exposure of

BCNU-treated PMN to an H_2O_2 -generating system resulted in an inhibition of chemotactic peptide-induced shape changes and degranulation. The ability of BCNU-treated cells to produce O_2^- was diminished only when the PMN were incubated with an H_2O_2 -generating system in the presence of cyanide. Ingestion of opsonized bacteria by BCNU-treated PMN was unaffected by incubation in an H_2O_2 -generating system even in the presence of cyanide. We conclude that (1) PMN GRED is inhibited by BCNU, (2) the ability of PMN to metabolize H_2O_2 is affected only when GRED is reduced more than 70%, (3) this inhibition affects the glutathione content of these cells, and (4) some, but not all of the phagocytic functions of GRED-inhibited PMN are inhibited after exposure to an H_2O_2 -generating system.

© 1987 by Grune & Stratton, Inc.

GRANULOCYTES (polymorphonuclear leukocytes, PMN) are thought to effect their bactericidal function through a respiratory burst¹ that results in the generation of reactive oxygen species²⁻⁴ mediated by the activity of a membrane-bound NADPH-dependent oxidase system.^{5,6} The reactive oxygen species may be toxic to other cells as well as to some aspects of PMN function.^{7,8} H_2O_2 has been implicated as one of the possible reactive oxygen species toxic to PMN function.^{8,9}

Jandl et al found a substantial increase in the oxidase activity if PMN were exposed to a stimulus under anaerobic conditions or in the presence of inhibitors of myeloperoxidase.¹⁰ Selenium-deficient rat PMN with diminished glutathione peroxidase activity manifested an increased sensitivity of their O_2^- generating system to either exogenous or endogenous H_2O_2 .¹¹ PMN of patients with a complete glutathione reductase (GRED) deficiency demonstrated an abbreviated oxidative burst with a greater and more rapid fall in reduced sulfhydryl content than normal PMN.¹²

The observation that 1,3-bis(2-chloroethyl)-nitrosourea (BCNU) selectively inhibits cellular GRED^{13,14} has permitted us to examine in depth the effects of GRED on PMN function. We have examined the effects of BCNU on PMN GRED activity, hexose monophosphate shunt (HMPS) activity, reduced sulfhydryl and glutathione content, and various aspects of phagocytic function in the presence and absence of an external source of H_2O_2 . This report describes the variable sensitivity of PMN function to BCNU-mediated inhibition of GRED.

MATERIALS AND METHODS

Materials

Ferricytochrome c type VI, superoxide dismutase (SOD), 5,5-dithio-bis-2-nitrobenzoic acid (DTNB), flavine adenine dinucleotide (FAD) NADPH, reduced glutathione (GSH), oxidized glutathione (GSSG), L-leucine, Concanavalin A type IV (ConA), N-formyl-methionylleucylphenylalanine (FMLP), *p*-nitrophenyl β -D-glucuronide, *o*-phthalaldehyde (OPT), methylene blue, N-ethyl maleimide (NEM), tertiary butyl hydroperoxide (t-BuOOH), nitroblue tetrazolium (NBT), glucose oxidase type X (GO), and L-amino acid

oxidase type V (LAAO) were purchased from Sigma Chemical Co, St Louis; dextran T-500 and Ficoll-Paque from Pharmacia Fine Chemicals, Piscataway, NJ; BCNU from Bristol Laboratories, Syracuse, NY; phytohemagglutinin (PMA) from Consolidated Midland Corp, Brewster, NY; zymosan from ICN Pharmaceuticals, Cleveland; cytochalasin B from Aldrich Chemicals, Milwaukee; and $1-^{14}\text{C}$ -glucose, $U-^{14}\text{C}$ -glucose and $U-^{14}\text{C}$ -L-leucine from New England Nuclear, Boston. All other reagents were obtained at the highest commercially available grade and used without further purification.

Preparation of PMN

Human peripheral blood PMN were prepared by dextran sedimentation and Ficoll-Paque centrifugation as previously described.¹⁵ The cells were kept at 2 to $5 \times 10^7/\text{mL}$ in phosphate-buffered saline (PBS: 135 mmol/L NaCl, 5 mmol/L KCl, and 10 mmol/L sodium phosphate buffer, pH 7.4) with glucose (5 mmol/L). Glucose was not present in the incubation mixtures if cytochalasin B or ConA were being used in the experiments or if HMPS activity was being measured. All assays involving PMN, except the spectrophotometric assays for O_2^- production, were performed in plastic containers.

Stock solutions were made as follows: ConA at 2 mg/mL in distilled water; PMA at 2 mg/mL in dimethyl sulfoxide (DMSO) and diluted to 20 $\mu\text{g}/\text{mL}$ in buffer; cytochalasin B at 1 mg/mL in DMSO; serum-treated zymosan (STZ) at 20 mg/mL in buffer after the treatment of zymosan with serum at 20 mg/mL for 30 minutes at

37 °C,¹⁶ and FMLP at 1 mmol/L in DMSO and diluted to various concentrations in buffer as needed.

Incubation of PMN With BCNU

PMN at a concentration of 1 to 2×10^7 /mL in PBS with glucose were incubated for ten minutes at 37 °C with varying concentrations of BCNU in DMSO or DMSO such that the final concentration of DMSO was always less than or equal to 0.5% of the total volume. After the ten-minute incubation, 5 vol of ice-cold PBS were added and the cells centrifuged at 500 g for ten minutes at 4 °C. The PMN were then washed once with 10 mL PBS and finally resuspended in PBS with or without glucose (as mentioned earlier) to the same cell concentration as initially used for the incubation. When additional incubations in glucose oxidase were performed, the cells were incubated at 37 °C for 20 minutes in PBS with glucose, with or without GO (80 µg/mL). This amount of GO resulted in a flux of H_2O_2 of 1.2 µmol/min/mL. After the incubation, the cells were washed once with PBS and resuspended at the concentrations desired in PBS with or without glucose.

GRED Activity

GRED was quantitated spectrophotometrically as described by Beutler.¹⁷ The assay cuvettes contained 100 µmol/L NADPH, 1 µmol/L FAD, and PMN in the presence of 0.05% Triton X-100, 50 mmol/L Tris, and 100 µmol/L EDTA at pH 8.0. The assay was started by the addition of 3.3 µmol/L GSSG to the sample cuvette only, with the total volume in both reference and sample being 1.0 mL.

HMPS Activity

PMN at a final concentration of 1×10^6 /mL were incubated for 30 minutes (unless otherwise stated in the Results section) at 37 °C in Krebs' Ringer's phosphate (KRP: PBS plus 1 mmol/L $CaCl_2$ and 1.3 mmol/L $MgSO_4$, pH 7.4) containing 1 mmol/L glucose and 0.1 µCi ^{14}C -glucose, either alone or in the presence of 1 mmol/L L-leucine and 0.1 U/mL LAAO, 0.1 mmol/L methylene blue, 1 µg/mL PMA, 4 mg/mL STZ, or varying amounts of t-BuOOH, all in a total volume of 1 mL in septum-stoppered test tubes with a suspended central well containing 0.2 mL hyamine hydroxide.¹⁸ At the end of the incubation, 2.0 mL of 5 mol/L H_2SO_4 was added and the incubation continued for an additional 30 minutes. The amount of LAAO used resulted in a flux of H_2O_2 of 60 nmol/min/mL. The trapped radioactive CO_2 was then quantitated in a liquid scintillation counter.

Nonprotein Reduced Sulphydryl Levels in PMN

PMN (1×10^7 in 1 mL) were rapidly centrifuged in a Fisher microcentrifuge. The resulting cell pellet was treated with 0.2 mL of 1.0% Triton X-100 and 0.3 mL of protein-precipitating solution¹⁹ and centrifuged for five minutes in a microcentrifuge at 4 °C. Reduced sulphydryl levels were obtained on the resulting supernatant using DTNB as described for erythrocytes by Beutler.¹⁹

GSH Levels in PMN

PMN were centrifuged, treated with Triton X-100 and the protein-precipitating solution, and clarified by centrifugation as earlier. The GSH levels were determined as described by Hissin and Hilf,²⁰ in which 0.01- to 0.1-mL samples were added to 0.1 mol/L sodium phosphate, pH 8.0, containing 0.1 mL of 0.1% OPT in absolute methanol in a final volume of 2.0 mL. After 15 minutes' incubation at 25 °C, the fluorescence of the samples was read in a Perkin-Elmer model 650-10S spectrofluorometer with the excitation wavelength set at 350 nm and the emission at 420 nm. GSH

standards were assayed at the same time. The recovery of GSH, determined by adding known amounts of GSH to the samples, was always greater than 90%.

Bipolarity Assay

The ability of PMN to respond to FMLP by assuming a bipolar shape was measured by modifications of a previously described technique.²¹ PMN were washed and resuspended at 5×10^5 /mL in PBS. Flat-bottomed 96-well tissue culture plates were coated with 50 µL of 1% bovine serum albumin (BSA) for 15 minutes at 37 °C. After removing the BSA solution, 50 µL of PMN was added and allowed to settle onto the plates on ice for 30 minutes. The cells were then warmed at 37 °C for five minutes, and FMLP or control solutions were added and incubated with the addition of 200 µL of cold 5% glutaraldehyde in 0.1 mol/L cacodylate buffer, pH 7.4. The supernatant was removed by aspiration after 15 minutes and replaced with fresh cacodylate buffer. The percentage of bipolar cells was counted using an inverted microscope.

Degranulation

STZ (4 mg) was added to 2×10^6 PMN in a final volume of 1.0 mL KRP in the presence of cytochalasin B (5 µg) for 30 minutes at 37 °C. The cells were then placed on ice and centrifuged and the supernatants assayed for the β -glucuronidase²² and lysozyme²³ content. Whole cells were also assayed for their enzyme content. All assays contained 0.05% Triton X-100. The specific degranulation was determined by subtracting the control supernatants from supernatants of zymosan-treated cells. As an index of cell lysis, the lactic dehydrogenase (LDH) release was measured.²⁴

Superoxide Production

Superoxide production by cells incubated as described was performed in a continuous spectrophotometric assay as previously described²⁵⁻²⁷ using either PMA (1 µg), ConA (100 µg), or STZ (4 mg) as the stimulus. In some assays, 0.1 mL cytochrome c was added to both sample and SOD-containing reference cuvettes either two or ten minutes after the addition of the stimulus to measure the rate of O_2 production at that time. PMA-stimulated NBT dye reduction was performed by incubating 2.5×10^6 PMN with 1 µg PMA in KRP buffer containing 0.04% NBT and 1% albumin in a total volume of 1.0 mL at 37 °C for five minutes. The reaction was terminated by the addition of 5 mL ice-cold PBS and the cells centrifuged at 280 g for five minutes. After washing the cells once, the cells were resuspended in 0.02 mL of 5% albumin and smeared on glass slides. The dried slide was fixed in methanol, dried again, and counterstained with 1% safranin for one minute. Two hundred consecutive cells were counted for formazan deposits.

Ingestion

The ingestion of ^{14}C -labeled *Escherichia coli* was measured in cells that had been incubated as described earlier using a modification of the method of Newburger et al.²⁸ ^{14}C -labeled bacteria were prepared by 24-hour growth of *E. coli* in minimum essential medium containing 3 mmol/L glucose, 100 µCi U- ^{14}C -glucose, and 50 µCi U- ^{14}C -L-leucine. Bacteria were washed, autoclaved, and resuspended at approximately 5×10^8 /mL. Prior to the assay, the bacteria were washed with saline, resuspended in 2 mL fresh human serum, opsonized for 30 minutes at 37 °C, and then washed free of serum. PMN (2×10^6) were incubated with opsonized bacteria (approximately 2×10^7) in KRP with and without 1 mmol/L NEM in the presence or absence of 0.5 mmol/L NaCN for 30 minutes at 37 °C. After the incubation 1 mmol/L NEM was added to all samples and the PMN washed three times with PBS followed by

centrifugation at 200 g for five minutes. The final pellets were counted in a liquid scintillation counter. Ingestion was corrected for adherence by subtracting the radioactivity of cells incubated in the presence of NEM from that in its absence. The results are expressed as counts per minute associated with the PMN.

RESULTS

The Effect of BCNU on PMN GRED Activity

Because BCNU has been shown to inhibit the GRED activity of mammalian cells, we determined its effect on this activity in PMN. PMN were incubated for ten minutes in the presence of varying concentrations of BCNU. The cells were then washed twice and assayed for GRED activity in the presence of 1.0 $\mu\text{mol/L}$ FAD (a cofactor for GRED) and 0.05% Triton X-100. We had previously shown that the Triton X-100 treatment of granulocytes results in complete expression of GRED activity but does not inhibit the enzyme activity. The results are presented in Fig 1. As can be seen, there is a concentration-dependent inhibition of PMN GRED by BCNU, with 50% inhibition occurring at approximately 2 $\mu\text{g/mL}$ BCNU. A ten-minute incubation was chosen because it ensured maximum inhibition and did not affect O_2^- production by activated PMN. Because BCNU inhibition of GRED requires a catalytically active enzyme,¹⁴ all inhibition values pertain to the assay of enzymatic activity in cell lysates made after incubation of the cells with BCNU. Incubation of PMN with 10 to 50 $\mu\text{g/mL}$ BCNU resulted in less than a 6% loss of viability when compared with control cells as assessed by either trypan blue exclusion or the retention of LDH.

The Effect of GRED Inhibition by BCNU on HMPS Activity

We determined the effect of BCNU on the ability of PMN to metabolize H_2O_2 through the glutathione cycle and the HMPS. We used L-leucine and L-amino acid oxidase as an exogenous H_2O_2 -generating system. Figure 1 compares the

Fig 1. Effects of BCNU on GRED and HMPS activity. PMN that had previously been incubated with DMSO or BCNU at the concentrations noted as described in Materials and Methods were assayed for GRED activity (Δ — Δ) or assayed for HMPS activity using either L-leucine plus LAAO ($\circ$ — $\circ$) or methylene blue ($\square$ — $\square$) as a stimulant. The results are reported as the percentage of activity in DMSO-treated cells. The values represent the means $\pm$ SD for between three and nine samples.

results obtained when comparing the effects of BCNU on both GRED (triangles) and H_2O_2 metabolism through the HMPS (circles). Significant inhibition of the metabolism of H_2O_2 does not occur until the GRED levels decrease to approximately 30% of the control values. Fifty percent inhibition of H_2O_2 metabolism occurs at approximately 8 $\mu\text{g/mL}$ BCNU.

To determine that the effect of BCNU was on the glutathione cycle and not the HMPS itself, we examined the effect of BCNU on the shunt directly. When methylene blue is added to cells, it directly oxidizes NADPH and thereby stimulates the HMPS. Figure 1 also shows the effect of BCNU on methylene blue-stimulated HMPS (squares). Methylene blue-stimulated HMPS activity in BCNU-treated PMN is approximately equal to control PMN at concentrations of BCNU that result in a 70% to 80% inhibition of both H_2O_2 metabolism and GRED activity. This indicates that the ability of the HMPS to function is not affected by BCNU concentrations that inhibit the glutathione cycle.

We also investigated the effect of BCNU on the ability of PMN to reduce known quantities of t-BuOOH. As can be seen in Fig 2, increasing concentrations of BCNU resulted in a progressive inability to reduce t-BuOOH by using the reducing equivalents generated through the HMPS.

For most of the studies to be reported, we tried to determine the effect of the diminished ability to metabolize H_2O_2 on PMN function. We therefore used a concentration of BCNU (10 $\mu\text{g/mL}$) that inhibited H_2O_2 metabolism by 70% but did not, even in the presence of an H_2O_2 -generating system, result in demonstrable cell lysis.

The Effect of GRED Inhibition on a Reduced Sulphydryl Content and Glutathione Content of PMN

Because GRED is involved in maintaining reducing equivalents in cells, we measured the effect of the incubation of PMN and BCNU (10 $\mu\text{g/mL}$) on a reduced sulphydryl

Fig 2. Effect of BCNU on the HMPS activity in response to t-BuOOH. PMN that had previously been incubated with DMSO ($\circ$), 2 μg BCNU ($\square$), 4 μg BCNU (∇), or 10 μg BCNU ($\times$) in 1 mL of PBS were washed and resuspended in PBS. The PMN were assayed for GRED activity, and the HMPS activity was measured in the presence of t-BuOOH at the concentrations noted. The values in parentheses refer to the percentage of control GRED activity found in these PMN after incubation with the aforementioned amounts of BCNU. The points represent the means $\pm$ SD for three determinations.

content. We compared BCNU-treated cells with control cells for their reduced sulfhydryl content and then incubated cells in either buffer or an H_2O_2 -generating system (glucose plus GO) in the presence and absence of cyanide. Reduced sulfhydryl levels were measured with DTNB, and the results are presented in Fig 3. The incubation of PMN with BCNU resulted in a decrease in the reduced sulfhydryl levels. Further incubation at 37 °C for 20 minutes in buffer did not dramatically change this level. After exposure to an H_2O_2 -generating system, the reduced sulfhydryl content of the control PMN did decrease. However, BCNU-treated PMN had a greater fall in their reduced sulfhydryl level than did the control PMN. The addition of cyanide to this system resulted in an accentuation in the decrease in reduced sulfhydryl level in BCNU-treated cells. We also investigated the effect of a phagocytic stimulus on the reduced sulfhydryl content in control and BCNU-treated PMN. The addition of STZ to control cells resulted in a depletion in the reduced sulfhydryl content. This effect was accentuated in BCNU-treated cells (data not shown).

We used the method of Hissin and Hilf²⁰ to determine the effect of BCNU inhibition of GRED on the GSH levels in PMN. Cells were treated in the same way as described earlier; the results are shown in Table 1. After incubation with BCNU, the GSH levels were decreased. With incubation in an exogenous H_2O_2 -generating system, the GSH levels were decreased to a greater extent in the BCNU-treated cells. Thus it appears that in the absence of adequate GRED activity GSH and other reduced sulfhydryls are diminished and are further affected by the addition of an exogenous source of H_2O_2 .

The Effect of GRED Inhibition on Phagocytic Function

FMLP-induced shape changes. It has previously been shown that the inability of PMN to change their shape and become bipolar is a very sensitive indicator of the effect of

Table 1. Effect of BCNU With or Without GO on the GSH Content of PMN

Incubation	GSH (nmol/10 ⁶ PMN)	
	DMSO	BCNU
None	2.90 ± 0.57*	1.95 ± 0.63*
20' PBS + Glu	2.70 ± 0.59†	1.83 ± 0.73‡
20' PBS + Glu + GO	2.49 ± 0.56†§	1.23 ± 0.70‡§

PMN (1×10^7) that had been incubated with DMSO or BCNU (10 μ g/mL) were then either directly assayed for the GSH and GSSG content or incubated for 20 minutes at 37 °C in PBS with 5 mmol/L glucose with or without GO (80 μ g) in a total volume of 1.0 mL. The PMN were then assayed for their GSH and GSSG content. The results are expressed as means ± SD for ten experiments. Statistics (paired *t* test) are presented for the comparisons of conditions as indicated by the superscripts.

the chemoattractant FMLP.²¹ We examined the effect of low (1 μ g/mL) and high (10 μ g/mL) concentrations of BCNU on this aspect of chemotactic responsiveness. This assay was chosen because it examined cells individually, and the effects of both sensitivity to FMLP and the total number of cells responding could be measured. Incubation of PMN with either 1 or 10 μ g/mL BCNU had no major effect on either the sensitivity of the cells to FMLP or the number of cells responding to FMLP, as can be seen in Fig 4. However, if cells treated with 10 μ g/mL BCNU were then treated with glucose plus glucose oxidase, many of the cells lost their ability to respond to FMLP. Of note is that neither the control cells nor cells treated with 1 μ g/mL BCNU were affected by exposure to an exogenous H_2O_2 -generating system. The effect of the high concentration of BCNU was on the number of cells responding to FMLP, not on the relative sensitivity of the cells responding. Thus, BCNU pretreatment can make some PMN more sensitive to the effects of an

Fig 3. Effect of BCNU on the reduced sulfhydryl content of PMN. PMN that had previously been incubated with DMSO or BCNU (10 μ g/mL) as described in Materials and Methods were assayed for reduced sulfhydryl content (A). Additional PMN (1×10^7) were incubated for an additional 20 minutes in PBS with 5 mmol/L glucose alone (B), with 80 μ g GO (C), or with 80 μ g glucose oxidase and 0.5 μ mol NaCN (D) in a total volume of 1.0 mL at 37°C prior to being assayed for reduced sulfhydryl content. The results are reported as the means ± SD for the number of samples as shown in the parentheses.

Fig 4. Effect of BCNU with or without GO on FMLP-induced PMN bipolarity. PMN (1×10^7) that had been incubated with DMSO (○,●), 1 μ g/mL BCNU (△,▲), or 10 μ g/mL BCNU (□,■) as described in Materials and Methods were then incubated for 20 minutes in PBS with 5 mmol/L glucose (solid lines) or in the same buffer containing 80 μ g GO (dashed lines) in a total volume of 1.0 mL. The PMN were then washed and assayed for a bipolarity response to the concentrations of FMLP noted on the abscissa. The results are the means of five experiments. SD are given only for the 10- μ g/mL BCNU samples.

H₂O₂-generating system such that they are unable to respond to FMLP with a shape change.

Degranulation. Degranulation was measured by examining the supernatants for the release of β -glucuronidase and lysozyme after stimulation with STZ in the presence of cytochalasin B. The effects of BCNU with and without exposure to an H₂O₂-generating system can be seen in Fig 5. Treatment of PMN with 10 μ g/mL BCNU resulted in a statistically significant ($P < .05$) decreased ability of these cells to degranulate in response to STZ. After the control and BCNU-treated cells were incubated in the presence of glucose plus GO, there was a decrease in their ability to degranulate in response to STZ. The BCNU-treated cells displayed a greater sensitivity to the exogenous H₂O₂-generating system than did the control cells ($P < .0005$). Qualitatively similar results were obtained when lysozyme release in response to STZ was measured (data not shown). These results are similar to those seen for the FMLP shape change and again indicate a sensitivity of BCNU-treated cells to the effects of an H₂O₂-generating system. In addition, studies we were able to determine that the degree of inhibition of the STZ-stimulated release of β -glucuronidase was dependent on the amount of GO used in the incubation when the amount of GO was varied from 1 to 80 μ g/mL. At each concentration, the inhibition was greater for the BCNU-treated cells when compared with the control cells.

Oxidative metabolism. To determine the effect of GRED inhibition on the ability of the cells to undergo an oxidative burst in response to stimuli, we examined the effect of BCNU treatment on O₂⁻ production by PMN stimulated with PMA, ConA, or STZ. Table 2 shows that BCNU treatment alone had no effect on the rate of O₂⁻ production by cells activated by any of the stimuli. Interestingly, even after incubation of the cells with glucose plus GO there was no alteration in the rate of O₂⁻ production with any of the stimuli. However, when cells were incubated in a glucose-plus-GO system in the presence of cyanide (an inhibitor of

Fig 5. Effect of BCNU on STZ-induced β -glucuronidase release from PMN. PMN (2×10^6) that had been incubated with DMSO or BCNU (10 μ g/mL) and then with PBS plus 5 mmol/L glucose with or without 80 μ g/mL GO and washed as described in Materials and Methods were incubated in KRP with 5 μ g cytochalasin B with or without 4 mg STZ in a total volume of 1.0 mL for 30 minutes at 37°C. The cells were centrifuged, and the amount of β -glucuronidase in the supernatants was determined after correcting for release in the absence of STZ. The results are expressed as the mean percent release $\pm$ SD of β -glucuronidase specifically released for four experiments.

PMN (2×10^6) that had been incubated with DMSO or BCNU (10 μ g/mL) were then incubated in PBS plus 5 mmol/L glucose alone or with 80 μ g GO with or without 0.5 μ mol NaCN for 20 minutes at 37 °C in a total volume of 1.0 mL. The cells were then washed and assayed for their ability to generate O₂⁻ in the presence of PMA (1 μ g), ConA (100 μ g), or STZ (4 mg) in KRP with 5 μ g cytochalasin B in a total volume of 1.0 mL. The results are the means $\pm$ SD for five experiments. The statistical analysis used the paired *t* test.

Abbreviation: ND, not determined.

* $P < .01$ when compared with no addition.

† $P < .001$ when compared with no addition.

‡ $P < .02$ when compared with no addition.

Other results are not statistically significantly different from no addition values.

catalase), the resulting rate of O₂⁻ production by BCNU-treated cells was diminished when compared with control PMN. Incubation of PMN in cyanide alone had no effect on their rate of O₂⁻ production (data not shown). Thus, although BCNU inhibition of GRED did affect the cells' ability to metabolize H₂O₂, it was not until an alternative method of metabolizing H₂O₂ was inhibited that oxidative metabolism was affected.

We used NBT dye reduction to determine whether the observed decrease in O₂⁻ production was due to an inability of a subpopulation of PMN to respond to a stimulus, as was seen in the bipolarity assay. With PMA as a stimulant, there was only a slight reduction in the number of NBT-positive cells, from 96% in control cells to 90% in BCNU-treated cells, that had been incubated with glucose plus glucose oxidase in the presence of cyanide. Using this assay, we noted that the intensity of the NBT positivity of the cells was markedly diminished in the BCNU-, glucose-, GO- and cyanide-treated cells.

Cytochalasin B was used in the investigations on O₂⁻ production because its presence is necessary for ConA-stimulated O₂⁻ production²⁶ and enhances the detection of O₂⁻ by STZ-stimulated PMN.²⁷ Cytochalasin B has no effect on PMA-stimulated O₂⁻ production. The inhibition of PMA-stimulated O₂⁻ production in BCNU-treated cells incubated in the presence of glucose plus GO with cyanide was also found in the absence of cytochalasin B.

Because PMN can produce their own H₂O₂ through the respiratory burst, we examined the effect of BCNU treatment on the duration of the respiratory burst by comparing the O₂⁻ production at two minutes after stimulation with the O₂⁻ production at ten minutes after stimulation. For this experiment, cytochrome c was not added until either two or

ten minutes because its presence precludes the dismutation of O_2^- to H_2O_2 . As can be seen in Table 3, the O_2^- production of BCNU-treated cells was diminished at ten minutes after stimulation with PMA when compared with the O_2^- production at two minutes. In contrast, there was no difference in the ratio of ten-minute to two-minute points when either STZ or ConA was used as a stimulus. Comparing BCNU-treated cells and control cells for stimulus-dependent HMPS activity as a function of time showed similar results. Figure 6 shows that there is a progressive decrease in the ratio of HMPS activity with time in BCNU-treated cells when compared with control cells when PMA was the stimulant. This effect was much diminished when STZ was used as a stimulant. The HMPS activity could not be assessed for ConA, because ConA inhibited the assay system even when dihydrocytochalasin B was used to enhance ConA stimulation of oxidative metabolism.

Ingestion. We next examined ingestion of opsonized ^{14}C -labeled *E. coli*. Ingestion as distinct from attachment, was measured by comparing the amount of radioactivity associated with the PMN in the presence and absence of 1 mmol/L NEM. The difference was used as an index of the number of *E. coli* ingested. As can be seen in Table 4, BCNU-treated cells displayed the same ability to ingest ^{14}C -labeled *E. coli* as did control cells. In addition, preincubation of the cells in glucose plus GO by using up to four times as much GO as used in the other studies had no effect on the ability of the cells (either control or BCNU-treated) to ingest these particles in either control or BCNU-treated cells, even in the presence of cyanide. Thus, despite the effects of BCNU and H_2O_2 on the GSH and reduced sulfhydryl content, degranulation, ability to respond to a chemoattractant, and oxidative metabolism, there was no effect of BCNU either with or without an H_2O_2 -generating system, even in the presence of cyanide, on the ingestion of ^{14}C -labeled *E. coli*.

Table 3. Effect of BCNU on the Rate of Decrease of PMN O_2^- Production

Stimulant	Ten-Minute Rates of O_2^- Production as a Percentage of the Two-Minute Rate		P
	DMSO	BCNU	
PMA	79.8 ± 17.3	40.6 ± 7.42	<.02
ConA	39.6 ± 17.0	37.2 ± 12.3	NS
STZ	81.1 ± 20.3	86.2 ± 18.3	NS

PMN (2×10^6) that had been incubated with DMSO or BCNU (10 μ g/mL) as described in Materials and Methods were washed and assayed for O_2^- production in KRP containing 5 μ g cytochalasin B and either PMA (1 μ g), ConA (100 μ g), or STZ (4 mg) in a total volume of 1.0 mL. The rates of O_2^- production were determined at two and ten minutes after the addition of the stimulant as described in Materials and Methods. The results are expressed as the means of the percentage of the ten-minute rate compared with the two-minute rate $\pm$ SD for four experiments. The control rates of O_2^- production in the absence and presence of BCNU respectively were 4.19 ± 0.65 and 3.85 ± 0.34 (PMA), 3.27 ± 0.39 and 2.88 ± 0.32 (ConA), and 3.94 ± 0.66 and 3.63 ± 0.83 (STZ) nmol O_2^- /min/ 10^6 PMN. The statistical analysis used the paired *t* test.

Abbreviation: NS, not significant.

Fig 6. Comparison of PMA and STZ stimulation of HMPS activity in BCNU- and DMSO-treated PMN. PMN (1×10^6) that had been incubated with DMSO or BCNU (10 μ g/mL) and washed were assayed for HMPS activity as described in Materials and Methods in the presence of PMA (1 μ g) (○) or STZ (4 mg) (Δ). At the times noted the reactions were terminated by the addition of 5 mol/L H_2SO_4 , and the $^{14}CO_2$ was measured. The results are expressed as the percentage of counts per minute in the BCNU-treated cells as compared with the DMSO-treated cells at each time point. The number of experiments for each time point are as noted in the parentheses. The upper numbers relate to the STZ experiments and the lower numbers to the PMA experiments.

DISCUSSION

The oxidative burst that accompanies phagocytosis is of short duration.^{10,29} This is probably important because the products of the oxidase system may be toxic to the host. It is believed that H_2O_2 , a product of the burst, is at least partially responsible for limiting its activity. The PMN of patients with complete GRED deficiency demonstrated an abbreviated respiratory burst with a greater and more rapid fall in the reduced sulfhydryl content than normal PMN.¹² Their PMN were unable to undergo an oxidative burst after exposure to an external H_2O_2 -generating system.

To further study the effects of inhibition of GRED on granulocyte function in general, we used the chemotherapeutic agent BCNU, which has been shown to selectively inhibit GRED.^{13,14} As with other cells, we were able to demonstrate a dose-dependent inhibition of cellular GRED by BCNU. The functional consequence of this inhibition, as measured by the ability of the cells to metabolize H_2O_2 , was not found until the GRED activity dropped to between 20% and 30% of control values. This is similar to what we had previously found in rats whose glutathione peroxidase activity was diminished after feeding them a selenium-deficient diet (Baker and Cohen, unpublished observation). Thus, there appears to be a threshold amount of GRED necessary to metabolize H_2O_2 , and this amount is less than that normally present in PMN.

GRED inhibition led to a decrease in the levels of both reduced sulfhydryls and GSH, which may be due to the ability of BCNU-derived alkylating species to directly conjugate with GSH.³⁰ The effect of BCNU on GSH was further accentuated by placing the cells in an H_2O_2 -generating system. This oxidative stress further diminished the GSH content in both control and BCNU-treated cells, but to a greater extent in the BCNU-treated cells. The addition of cyanide to inhibit catalase, which might also be involved in H_2O_2 metabolism, made this effect even more pronounced. The same effect on a reduced sulfhydryl content was seen

Table 4. Effect of GO With or Without NaCN on the Ability of DMSO- or BCNU-Treated PMN to Ingest *E coli*

Incubation	GRED (U/mL/10 ⁷ PMN)	Ingestion (cpm/30 min/2 × 10 ⁶ PMN)		
		Control	GO	GO + NaCN
DMSO	38.4 ± 1.9	10,134 ± 1,163	9,024 ± 1,223	10,908 ± 1,702
BCNU	2.5 ± 0.8	10,528 ± 1,139	10,282 ± 1,418	10,890 ± 1,066

PMN (2 × 10⁶) that had been incubated with DMSO or BCNU (25 µg/mL) were washed and incubated in PBS with 5 mmol/L glucose alone or with 80 µg GO with or without 0.5 µmol NaCN in a total volume of 1.0 mL as described in Materials and Methods. The cells were washed and incubated in KRP containing 5 mmol/L glucose with ¹⁴C-labeled *E coli* that had been opsonized with fresh human serum with or without 1 µmol NEM as described in Materials and Methods. The results are the means ± SD for three experiments. The GRED activity was determined in PMN following incubation in either DMSO or BCNU (25 µg/mL).

when H₂O₂ was generated endogenously by incubating the cells with STZ. Thus, GRED plays an important role in maintaining the levels of PMN reduced sulphydryls and GSH in both the resting and H₂O₂-stressed state.

The effect of the inhibition of GRED and consequent diminution in the reduced sulphydryl content on various aspects of phagocytosis was examined. The results indicate that the various phagocytic functions displayed different sensitivity to GRED inhibition. Prior treatment of cells with BCNU did not affect the responsiveness of cells to a chemoattractant, the ability of cells to undergo oxidative metabolism or to ingest bacteria. The ability of PMN to degranulate in response to a phagocytic stimulus was diminished in BCNU-treated cells. Premature termination of the respiratory burst was found only in BCNU-treated cells that were stimulated with PMA, but not in those stimulated with STZ or ConA. Because stimulation of PMN with PMA occurs by a mechanism different from those associated with other stimulants of the respiratory burst,³¹ this system may be more sensitive to unmetabolized H₂O₂. The amount of GO necessary to produce a sufficient flux of H₂O₂ to produce inhibition of phagocytic function in BCNU-treated cells was much higher than that produced endogenously. This may explain why, with the exception of PMA, there was no premature termination of the respiratory burst and why most other phagocytic functions were unaffected by BCNU alone. The O₂⁻ production by control PMN was lower than that previously reported.²⁵⁻²⁷ We believe that this was due to the multiple incubations and washings required to perform these studies. The stress of an exogenous H₂O₂-generating system on BCNU-treated cells resulted in alterations of some phagocytic functions but not with all functions studied. Thus, responsiveness to a chemoattractant and degranulation

occurred less well in BCNU-treated cells that had been incubated in the presence of glucose plus GO. O₂⁻ production and ingestion were unaffected by this incubation in an exogenous H₂O₂-generating system. However, O₂⁻ production, but not ingestion, was altered when the GO incubation was performed in the presence of cyanide, an inhibitor of catalase. These results indicate that the sensitivity of PMN to H₂O₂ in the presence of decreased GSH is dependent both on the nature of the stimulant and the aspect of phagocytic function.

When comparing the results obtained on O₂⁻ production, ingestion, and degranulation in human PMN treated with BCNU with PMN obtained from glutathione peroxidase-deficient rats,³² it appears that the rat cells are more sensitive to the loss of function of the glutathione cycle. This may be due to the fact that rat PMN are devoid of catalase³³ and thus have no alternative pathway for metabolizing H₂O₂.

It must be noted that, with the exception of degranulation, there was no effect of BCNU alone on any of the phagocytic functions measured. The only instances in which inhibition of phagocytic functions were noted were when the cells were stressed, either endogenously or exogenously, with H₂O₂. Therefore, with the exception of the effect of BCNU on the reduced sulphydryl content, we postulate that the effects of BCNU, as noted, are due to inhibition of GRED and, consequently, H₂O₂ metabolism.

The use of inhibitors of various aspects of the glutathione cycle can be helpful in dissecting the effects of H₂O₂ on components of phagocytosis. However, it is important to realize that these various components display different sensitivity to BCNU and H₂O₂ and that some of the sensitivity may in part be dependent on other protective mechanisms present in PMN.

Combinations of Recombinant Human Interferons and Retinoic Acid Synergistically Induce Differentiation of the Human Promyelocytic Leukemia Cell Line HL-60

By Hiromichi Hemmi and Theodore R. Breitman

The human acute promyelocytic leukemia cell line HL-60 is induced to differentiate into morphologically and functionally mature monocytelike cells by incubation with a combination of 10 nmol/L retinoic acid (RA) and various concentrations of recombinant immune interferon (rIFN- γ). These induced cells show marked increases in antibody-dependent cellular cytotoxicity (ADCC), antibody-coated erythrocyte (EA) rosettes, nonspecific esterase, and 5'-nucleotidase activity. rIFN- γ alone at concentrations of 10 to 1,000 U/mL has essentially no effect on morphological maturation, nitroblue tetrazolium reduction, and immunophagocytosis. However, rIFN- γ at these concentrations increases EA rosetting in a concentration-dependent manner that is not affected by 10 nmol/L RA. At a concentration of 1,000

U/mL, rIFN- γ induces moderate increases in nonspecific esterase, 5'-nucleotidase, and ADCC. These parameters are markedly increased by the addition of 10 nM RA, a concentration which alone has no effect on these markers. Based on units of antiviral activity, rIFN- γ is tenfold more active than rIFN- α D in inducing EA rosettes and 40-fold more active in inducing nitroblue tetrazolium reduction and immunophagocytosis. These results, indicating that combinations of rIFN- γ or rIFN- α and RA synergistically induce differentiation of HL-60, suggest that this combination may have clinical utility in the treatment of patients with certain leukemias.

This is a US Government work. There are no restrictions on its use.

THE HUMAN ACUTE PROMYELOCYTIC leukemia cell line HL-60¹ is a useful model system for studying the differentiation of human myelomonocytic cells.² HL-60 is induced to differentiate into granulocytelike cells by incubation with a wide variety of compounds including dimethyl sulfoxide (DMSO) and retinoic acid (RA)¹⁻³ or into monocyte (macrophage)-like cells by incubation with 1 α ,25-dihydroxyvitamin D₃ and phorbol diesters.⁴⁻⁶ HL-60 is also induced to differentiate into cells having many characteristics of monocyte (macrophage)-like cells by conditioned media of either mitogen-stimulated normal human peripheral blood mononuclear cells or of mixed-lymphocyte cultures.⁶⁻¹² Changes include increases in the percentage of cells positive for nonspecific esterase, having Fc and C3 receptors, capable of immunophagocytosis, reducing nitroblue tetrazolium (NBT), having antibody-dependent cellular cytotoxicity (ADCC), expressing various surface antigens of monocytes or macrophages, and maturing morphologically. Several groups have found that interferon (IFN)- γ , a component of activated lymphocyte-conditioned media, has similar effects on HL-60¹³⁻¹⁸ and the suggestion has been made that this lymphokine is the active component.¹⁴ However, it is apparent from other studies that there are also lymphokines present, distinct from IFN- γ , that have a similar activity.¹⁶⁻¹⁸ We have named these lymphokines "differentiation-inducing activity" (DIA).² A DIA that we have studied was originally described by Olsson and Olofsson¹⁰ and partially purified from normal human stimulated mononuclear cells¹¹ and from the conditioned medium of the malignant T lymphocyte line HUT-102.¹⁹ Although this DIA alone, at a relatively high concentration, induces the differentiation of HL-60, its most remarkable effect is its ability at a relatively low concentration and in combination with the normal plasma concentration of RA (10 to 30 nmol/L) to increase the differentiation of HL-60^{2,19} and fresh cells from patients with acute promyelocytic leukemia.² The findings that IFN- γ appears to have a similar activity prompted the present investigation to study combinations of IFN and RA. A preliminary report on some of the findings in this study has been published.²⁰

MATERIALS AND METHODS

The HL-60 cell line (passages 18 and 28) was maintained in polystyrene tissue culture flasks containing a growth medium consisting of RPMI 1640 medium supplemented with 10% fetal bovine serum (FBS). For experiments, the cells were harvested by centrifugation and resuspended in a serum-free defined medium consisting of RPMI 1640 medium supplemented with 5 μ g bovine insulin/mL and 5 μ g human transferrin/mL²¹ at an initial cell density of 2.5 to 3 $\times 10^5$ /mL. The cells were grown at 37°C in a humidified atmosphere of 5% CO₂ in air for four days. The cell number was determined with a Coulter Counter, and the viability was determined by trypan blue dye exclusion. RA (all-*trans*- β -retinoic acid, Sigma Chemical Co, St Louis) was dissolved in 100% ethanol and diluted at least 1,000-fold into the growth medium such that the final concentration of ethanol was no higher than 0.1%. Manipulations were in subdued light. Recombinant (r) human IFNs were provided by Dr Sidney Pestka and had the following specific activities (U/mg protein): rIFN- α A, 3 $\times 10^8$; rIFN- α D, 5 $\times 10^7$; and rIFN- γ , 2.6 $\times 10^7$. rIFNs were diluted in RPMI 1640 medium supplemented with 10% FBS. The highest concentration of FBS in the cultures was 0.25%. Measurements of NBT reduction, immunophagocytosis, antibody-coated erythrocyte (EA) rosettes, 5'-nucleotidase (EC 3.1.3.5), and morphology were performed as described in detail.²¹ ADCC against chicken red blood cells (CRBC) was assessed by the method of Perlmann et al.²² CRBC (1 $\times 10^8$) coated with a 1/125 dilution of rabbit IgG against CRBC (Cappel Laboratories, Cochranville, PA) were labeled with 300 μ Ci of ⁵¹Cr (New England Nuclear, Boston) for 1.5 hours at 37°C, washed by centrifugation with phosphate-buffered saline (pH 7.2), and resuspended at a cell concentration of 10⁵/mL in RPMI 1640 containing

Fig 1. Increases in EA rosettes (Δ , $\blacktriangle$), immunoe erythrophagocytosis ($\square$, $\blacksquare$), and NBT reduction ($\circ$, $\bullet$) of HL-60 cells treated with recombinant IFN- γ alone (open symbols) and in combination with 10 nmol/L RA (closed symbols).

10% FBS. To wells of a 96-well round-bottomed microtiter plate (Linbro Scientific Co, Hamden, CT) 100 μ L of this radiolabeled CRBC suspension (containing 10^4 CRBC/well) was mixed with an equal volume of effector cells suspended in RPMI 1640 containing 10% FBS. Quadruplicates were performed for each condition. The plates were incubated for four hours at 37 $^{\circ}$ C in a humidified atmosphere of 5% CO_2 in air. After incubation the plates were centrifuged, and 100 μ L of the supernatant fraction, containing the ^{51}Cr released from lysed CRBC, was collected and counted in a gamma-radioactive counter. The percent specific cytotoxicity (SC) was calculated according to the formula: Percent SC = $[(S - SR) / TC] \times 100$ where S is the cpm of the sample, SR is the cpm released from target cells (CRBC) alone, and TC is the total cpm in 50 μ L of labeled CRBC. The nonspecific esterase (NSE) was determined with the esterase kit obtained from Sigma Chemical Co by using α -naphthyl acetate as a substrate.

Unless otherwise indicated, data points represent the mean values of at least three determinations in a single experiment. Each

experiment was performed at least two times, and most experiments were repeated at least four times with consistent results.

RESULTS

We studied the effects of rIFN- γ alone and in combination with 10 nmol/L RA on three functional parameters and four other differentiation markers of mature myelomonocytic cells. rIFN- γ alone at concentrations of 10 U/mL or higher increases the percentage of cells forming EA rosettes (Fig 1) and at higher concentrations (1,000 U/mL) increases phagocytosis (Fig 1), the activities of NSE and 5'-nucleotidase, the number of cells with a morphology of monocytelike cells (Table 1), and ADCC (Fig 2) but has essentially no effect on the percentage of cells reducing NBT (Fig 1). The combination of 10 nmol/L RA and rIFN- γ markedly increases the extent of all myelomonocytic differentiation markers compared with the effect of each of these agents alone (Figs 1 and 2 and Table 1). HL-60 treated with 300 nmol/L RA shows increases in both the percentage of cells reducing NBT and maturing morphologically to granulocytelike cells (Table 1) but exhibits essentially no increase in the ADCC or either in 5'-nucleotidase or NSE, two enzyme markers of monocytes/macrophages (Fig 2 and Table 1). rIFN- α D alone, to a concentration of 5,000 U/mL, does not increase the percentage of cells that reduce NBT or are positive for immunophagocytosis. However, a concentration-dependent increase in EA rosetting is observed (Fig 3). At a concentration of 5,000 U/mL of either rIFN- α A or rIFN- α D there is a low percentage of cells expressing NSE activity and maturing to more mature forms (Table 1). Combinations of 10 nmol/L RA and either rIFN- α A or rIFN- α D increase all of these parameters, except for EA rosetting, to values that are greater than what would be expected from an additive effect (Fig 3 and Table 1). Based on U/mL, rIFN- α A and rIFN- α D are much less active than rIFN- γ .

There is no substantial growth inhibition of HL-60 by any of the three rIFNs (Fig 4A and B). There is a maximum growth inhibition of 20% (80% of control) with the rIFN- α s at concentrations of 500 U/mL and higher (Fig 4B), whereas rIFN- γ to a concentration of 3,000 U/mL does not inhibit

The cultures were incubated for four days.

Fig 2. ADCC of HL-60 induced by IFN- γ and RA. HL-60 cells were incubated for four days with none (○), 300 nmol/L RA (●), 10 nmol/L RA (▲), 1,000 U IFN- γ /mL (□), and 1,000 U IFN- γ /mL plus 10 nmol/L RA (■). Normal human peripheral blood mononuclear cells (Δ) were used as a positive control. Under the same conditions there was no spontaneous cytotoxicity of the HL-60 cells against either K-562 or Molt-4.

growth (Fig 4A). In the presence of 10 nmol/L RA, 3,000 U/mL of rIFN- γ decreases the growth to 70% of control compared with a value of 83% of control obtained with 10 nmol/L RA alone (Fig 4A). In the presence of 10 nmol/L RA, the growth of HL-60 with concentrations of rIFN- α s at 3,000 U/mL is approximately 60% of the control growth, and this value decreases to 53% of control at a concentration of 100,000 U rIFN- α D/mL. Under all of these conditions the viability was greater than 80%.

Fig 3. Increases in EA rosettes (Δ, ▲), immunoelectrophagocytosis (□, ■), and NBT reduction (○, ●) of HL-60 cells treated with IFN- α D alone (open symbols) and in combination with 10 nmol/L RA (closed symbols).

Fig 4. Growth of HL-60 in the presence of IFNs and RA. (A) Growth in the presence of rIFN- γ alone (○) and in combination with 10 nmol/L RA (●). (B) Growth in the presence of rIFN- α A (○, ●) or rIFN- α D (Δ, ▲) alone (open symbols) and in combination with 10 nmol/L RA (closed symbols). The values in parentheses are the number of independent experiments. The bars are the SD. The points with no bars are from one experiment. The mean initial cell concentration was $3 \pm 0.34 \times 10^5$ cells/mL. The mean control cell concentration at day 4 was $10.7 \pm 2.1 \times 10^5$ cells/mL.

DISCUSSION

The major finding in this study is that a combination of RA with either IFN- γ , IFN- α A, or IFN- α D is synergistic for inducing monocytic differentiation of HL-60. There have been many reports on the effects of the IFNs on HL-60 and other human myelomonocytic cell lines. To our knowledge this is the first report to describe the synergistic effects on HL-60 of IFN- γ in combination with RA.

IFN- γ alone increases the concentration of several surface markers including Fc receptors,^{13,14,18,23,24} HLA-DR antigens,^{25,26} chemotactic peptide receptors,¹⁸ and various monocyte-related antigens defined by monoclonal antibodies.^{14,18,24} The increase in the concentration of Fc receptors on HL-60, measured either directly as the number of IgG1-binding sites per cell or indirectly as the percentage of cells forming EA rosettes, is a relatively rapid response to IFN- γ with a maximum increase within 18 hours^{14,23} and with an ED₅₀ (concentration required for a half-maximal effect) of between 6 U/mL¹³ and approximately 40 U/mL.²³ With a four-day incubation period, we find that the ED₅₀ is 40 U/mL (Fig 1). This dose response is not affected by the addition of 10 nmol/L RA even though RA alone at this concentration gives a small increase in Fc-positive cells (Fig 1) and gives values >50% at higher concentrations.² In contrast to other studies^{13,23,24} we find that exposure to IFN- α D results in large increases in the percentage of cells that form EA rosettes (Fig 3). Although Guyre et al¹³ report a 1.6-fold increase in the concentration of Fc receptors on HL-60 after less than a one-day exposure, this increase was observed only at a very high concentration of 10,000 U rIFN- α /mL. Our longer exposure condition is not necessarily an explanation of these differences because it has been demonstrated that even after five days' exposure to 1,000 U rIFN- α /mL there is essentially no increase in Fc recep-

tors.^{23,24} There is no obvious explanation for these differences in results on IFN- α induction of Fc receptors except for the possibility that serum, used in the other studies and not in ours, inhibits the IFN- α induction of Fc receptors. The induction of Fc receptors by rIFN- α A and - α D has been a reproducible finding in our laboratories for over 3 years. In addition, there are increases in two Fc receptor-dependent functions, immunoerythrophagocytosis (Fig 3) and ADCC,²⁷ when HL-60 is exposed to rIFN α in the presence of 10 nmol/L RA. These differences in findings on IFN- α -associated changes in surface antigens are not limited to Fc receptors because IFN- γ is reported either to markedly increase the expression of HLA-DR^{25,26} or to have no effect.²⁴ An increase in the DR antigen is not observed for IFN- α and - β ²⁴⁻²⁶ or for RA, DMSO, or 12-O-tetradecanoylphorbol-13-acetate (TPA).^{12,25} An increase is observed with 1,25-dihydroxyvitamin D₃.²⁵

NSE and the plasma membrane-associated 5'-nucleotidase are two enzyme markers generally accepted to characterize the monocyte/macrophage.²⁸ The 5'-nucleotidase activity increases 55-fold in cells exposed for four days to 1,000 U IFN- γ /mL, and the combination of IFN- γ and 10 nmol/L RA results in an additional fourfold increase in this activity (Table 1). RA alone, either at 10 nmol/L or at 300 nmol/L, does not increase the 5'-nucleotidase activity. Our results with NSE activity (Table 1) are in agreement with Koeffler et al²⁵ and Dayton et al²⁴ who found increases in NSE-positive cells after five to six days of exposure to 1,000 U IFN- γ /mL. A concentration of 100 U/mL is without effect.^{25,29} Thus, although IFN- γ alone, at concentrations of 100 U/mL or less and at relatively short exposure times, induces increases in Fc receptors and HLA-DR, other mature markers of monocytic cells, eg, NSE, do not increase even after four to six days of exposure. At higher concentrations of IFN- γ (1,000 U/mL and higher) there are increases in 5'-nucleotidase and NSE. Exposure of the cells to a combination of 10 nmol/L RA and 1,000 U IFN- γ /mL increases markedly the levels of NSE and 5'-nucleotidase compared with the activities with each agent alone (Table 1). Two other studies report increases in the percentage of NSE-positive cells induced by IFN- γ .^{14,16} In contrast to two other studies^{24,25} we find that IFN- α alone induces a moderate increase in the percentage of cells that are NSE-positive (Table 1). As was the case with IFN- γ , this parameter is increased further by combinations of RA and IFN- α .

Our results on an increase in ADCC by IFN- γ (Fig 2) are in agreement qualitatively with those of Ball et al¹⁴ and Dayton et al.²⁴ ADCC is an activity associated with granulocytes and monocytes/macrophages. It therefore is of interest that HL-60 induced with RA alone at concentrations up to 300 nmol/L has essentially no ADCC activity (Fig 2). A similar finding was reported by Dayton et al¹² for HL-60 induced with 100 nmol/L RA for five days. Because RA induces HL-60 to granulocytelike cells, these results could indicate that the HL-60 granulocyte is deficient in ADCC. In support of this possibility are the findings that DMSO fails to induce ADCC in HL-60.^{14,30} However, it has also been reported that DMSO induces HL-60 to cells with moderate levels of ADCC activity¹² and that monocytoid

cells induced by TPA have essentially no ADCC activity.^{12,30} The combination of 10 nmol/L RA with either IFN- α A or IFN- α D results in the induction of cells with monocytoid characteristics (Table 1 and Fig 3). However, this combination, even with an IFN- α D concentration of 100,000 U/mL, gives only a very small increase in ADCC.²⁷ These results extend those reported previously that IFN- α at a concentration of 1,000 U/mL does not increase the ADCC activity of HL-60.²⁴

A review of the literature on the effects of IFN on the morphology and growth inhibition of HL-60 indicates major differences. Except for one report³¹ there is unanimity that HL-60 is induced by IFN- γ to differentiate to monocytoid cells.^{14,16,32,33} The extent of this change at concentrations of 1,000 U/mL is relatively low. We classified 8% of the cells as monocytes after a four-day exposure (Table 1), whereas Koeffler et al²⁵ found 17% after a six-day exposure. The percentage of monocytes is greatly increased after incubation of HL-60 with the combination of 10 nmol/L RA and 1,000 U IFN- γ /mL (Table 1). IFN- α alone has essentially no effect on changes in morphology (Table 1), in agreement with other reports.^{24,27,32,34} However, in combination with 10 nmol/L RA an increase in morphological maturation is observed (Table 1). Based only on the morphological changes that we saw in the presence of RA and IFN- α it appears that monocytes and more mature granulocytes are formed. However, based on the percent NSE, which is a more objective test for monocytes, it is probable that most of the intermediate granulocyte forms are monocytoid. It is likely that a similar difficulty in distinguishing between intermediate granulocytes and monocytoid cells by light microscopy was also the case with combinations of 10 nmol/L RA and concentrations of IFN- γ <1,000 U/mL.

There have been equivocal results on the inhibition of the growth of HL-60 by the IFNs. Our results (Fig 4A) indicate that IFN- γ alone does not inhibit the growth measured after a four-day incubation period. These results are in agreement with several studies in which the growth or proliferative ability was measured three to six days after the addition of a single dose of IFN- γ .^{14,16,24,29,35} In contrast to these results, four groups report a marked inhibition of the growth of HL-60 by IFN- γ .^{18,31,33,36} In each of these studies natural (n)IFN- γ was used, the incubation period was longer than four days, and/or fresh IFN- γ was added to the cultures during the test period. The greater stability of nIFN- γ compared to rIFN- γ under culture conditions is probably an explanation for these differences.³⁶

The relatively large inhibitory effects on the growth of HL-60 of approximately 50% at concentrations of 500 to 5,000 U IFN- α /mL reported by two groups^{31,32} has not been observed by us (Fig 4B) or by others.^{14,24,34,36} In the presence of 10 nmol/L RA, IFN- α had only a relatively small growth-inhibitory effect (Fig 4A). At a concentration of 3,000 U IFN- α /mL, the growth was 85% of that observed with 10 nmol/L alone. This apparent high growth potential in a population of cells that have many markers associated with terminally differentiated myeloid cells (Table 1, Figs 1 and 2) indicates that the loss of growth potential is a late event in the maturation process. The growth inhibition by

IFN- α in the presence of 10 nmol/L RA (Fig 4B) appears to be greater than that of IFN- γ , especially if comparisons are made at IFN concentrations that induce similar levels of maturation. Thus, it is possible that a portion of the growth inhibition by IFN- α is not related to terminal differentiation.

Our results on the effects of a combination of 10 nmol/L RA and IFN- α confirm and extend those reported by Grant et al.³⁷ These workers found that a combination of 100 nmol/L RA and 1,000 U IFN- α /mL increased by twofold the percentage of cells reducing NBT, from 42% with 100 nmol/L RA alone to 89% with the combination. IFN- α alone did not increase this parameter over the seven-day incubation period. Our results with 10 nmol/L RA in combination with various concentrations of IFN- α also show the apparent synergistic effect not only on NBT reduction but also on phagocytosis, morphology, NSE (Fig 3, Table 1), and more recently on ADCC.²⁷ The marked increase in NSE expression indicates that under our conditions the mature cells are monocytes. No designation of lineage is given by Grant et al.^{32,37} In another study using combinations of RA and IFN- α Tomida et al.³⁴ found after a four-day incubation period that a combination of 40 nmol/L RA and 1,000 U IFN- α /mL had essentially no effect on increasing the percentage of cells maturing beyond the promyelocyte stage compared with the condition with 40 nmol/L RA alone. However, they did find a shift to more mature granulocytes based only on light microscopy evaluation. Because no additional assays were performed to confirm these morphological changes, a shift in the direction of differentiation, from granulocytes in the presence of RA alone to monocytes in the presence of RA and IFN, may have occurred. Under our conditions of 10 nmol/L RA and either IFN- α or IFN- γ there is a shift to the monocyte lineage. It will be of interest to explore in greater depth the question to which lineage HL-60 matures in the presence of various concentrations of RA and IFN.

Recent reports on the binding parameters of the IFNs to lymphocytic and myeloid cells, including HL-60,^{35,38-42} allows us to make some correlations of the biologic effects we and others have observed with the kinetic parameters for IFN binding and the concentration of receptors on the cell plasma membrane. The dissociation constant (K_D) of rIFN- γ for its receptor is approximately 0.4 nmol/L, with approximately 4,000 receptors/HL-60 cell.^{38,40} Based on the specific activity of the rIFN- γ used in this study and a molecular weight of 17,500, a concentration of 0.4 nmol/L is equivalent to 180 U/mL. This concentration of IFN- γ alone increases the Fc receptor concentration of HL-60 and in the presence of 10 nmol/L RA increases the percentage of cells

reducing NBT and capable of phagocytosis (Fig 1). Thus, biologic effects are observed at a concentration of IFN- γ at which 50% of its receptors are occupied and the extent of these effects is closely related to the expected level of receptor occupancy. A similar conclusion can also be made for IFN- α based on a K_D of 0.25 nmol/L.^{42,43} In addition, during RA- or DMSO-induced differentiation of HL-60, the number of IFN- α -binding sites per cell increases almost threefold from 600 to 1,600.⁴³ Because of the expected positive relationship between the receptor number and the extent of a response, cells with a greater number of receptors would exhibit dose-response curves for IFN- α that are shifted to lower concentrations. This in part, may be an explanation for the synergy of combinations of RA and IFN- α . A similar increase in the concentration of IFN- γ receptors has not been observed during differentiation induced with either RA,⁴³ DMSO,^{40,43} or TPA.⁴⁰

Acute myelogenous leukemia has been viewed as a disease involving a block in the normal maturation of myeloid cells. Thus, it is possible that some leukemia cells do not mature either because they have a decreased ability to respond to exogenous differentiative factors or because the production of specific gene products obligatory for differentiation is altered. It is now clear, at least for some human myelomonocytic cell lines, that this block in maturation is not permanent and that incubation with physiological agents promotes end-terminal differentiation. These findings have generated interest in the induction of differentiation as an alternative approach to the treatment of some leukemias. Previous studies have shown that the differentiation of HL-60 in the presence of 10 nmol/L RA is markedly potentiated by agents, including cholera toxin, dibutyryl cyclic adenosine monophosphate (cAMP), and prostaglandin E, that increase the intracellular concentration of cAMP.² In addition, HL-60 is primed to respond to these agents, including the lymphokine DIA, by incubation with 10 nmol/L RA alone.⁴⁴ Fresh cells from patients with acute promyelocytic leukemia are induced to differentiate in primary culture by RA,⁴⁵ and combinations of RA and DIA are even more effective.² Thus, the finding in this and other studies that rIFNs have DIA means that the availability of DIA is not a problem for clinical studies. Recombinant technology should also allow for the construction of new DIAs having greater specificities and/or less toxic side effects.

ACKNOWLEDGMENT

We thank S. Pestka for supplying the recombinant interferons used in this study and T. Hattori and C. Grandori for help on the ADCC assay.

Differentiation of Blast Cells From a Down's Syndrome Patient With Transient Myeloproliferative Disorder

By Junko Suda, Mitsuoki Eguchi, Yoshihiro Akiyama, Yoshihiko Iwama, Toshiharu Furukawa, Yuko Sato, Yasusada Miura, Toshio Suda, and Masaki Saito

A male neonate with Down's syndrome and congenital myeloproliferative disorder was studied. His blood picture showed the unique coexistence of leukocytosis with matured cells and a large number of blast cells. The *in vitro* proliferation and differentiation of blast cells into various lineages in the presence of phytohemagglutinin-stimulated leukocyte conditioned medium (PHA-LCM) was examined by using a liquid culture and a methylcellulose culture system. The differentiation of blast cells into myeloid cells was confirmed by specific cytochemical stainings, electron microscopy, and an immunologic study. No specific factors in the plasma of the patient promoted the proliferation or differentiation of blast cells. The cellular composition of colonies grown in methylcellulose culture from single blast cells was studied by a micromanipulation technique. High

plating efficiency was observed. Of 136 cultures, 78 showed colony growth. Half of the blast cells were colony-forming cells that could proliferate and differentiate into basophils, neutrophils, eosinophils, macrophages, and erythrocytes in the presence of PHA-LCM. Using the blast cells with a high differentiation capacity to the basophil pathway, we studied the effect of recombinant granulocyte-macrophage colony-stimulating factor (GM-CSF). Recombinant GM-CSF support neutrophils, eosinophils, and macrophages but not typical basophils. These findings of the cell differentiation of blast cells into various kinds of cells *in vitro* were in agreement with the finding of neutrophilia, eosinophilia, basophilia, and thrombocythemia in this patient.

INFANTS WITH DOWN'S SYNDROME are predisposed to the myeloproliferative disorder.¹⁻⁶ This myeloproliferative disorder is characterized as follows: (1) the disorder is usually transient and putatively benign; (2) it is not associated with anemia, neutropenia, or thrombocytopenia, despite the presence of many blast cells in the peripheral blood; (3) the percentage of blast cells is greater in the blood than in the bone marrow; and (4) the blast cells demonstrate trisomy 21 with no other cytogenetic abnormalities. The nature of this disorder has been the subject of continued controversy.^{7,8} The etiologic relationship between the leukemoid reaction and acute leukemia is obscure. Because blast cells have no signs of differentiation, the lineage to which these cells belong has not been defined. The capacity of proliferation and differentiation of blast cells has not been clarified yet.

Recently, we encountered a patient with Down's syndrome who showed marked neutrophilia, basophilia, and thrombocythemia with increased numbers of blast cells. We characterized the pattern of proliferation and differentiation of blast cells using the single-cell culture method. Cytochemical, ultrastructural, immunologic, and gene rearrangement studies were done.

CASE REPORT

A 9-day-old boy had typical findings of Down's syndrome with marked hepatosplenomegaly and heart murmur. His hemoglobin level was 18.8 g/dL, and his WBC count was 61,600/ μ L with 62% blasts, 1% promyelocytes, 1% myelocytes, 1% metamyelocytes, 18% segmented neutrophils, 6% eosinophils, 4% basophils, and 7% lymphocytes. Erythroblasts were seen in the peripheral blood. The platelet count was 354,000/ μ L. The bone marrow examination showed a normal maturation of all cell lines despite the presence of 33% blasts. The neutrophil alkaline phosphatase score was within normal limits. A myeloproliferative disorder was diagnosed, and no specific therapy was given. The peripheral WBC increased to 144,000/ μ L with 67% blasts, 10% segmented neutrophils, 10% eosinophils, 3% basophils, and others within 1 month. Platelets also increased to 1,190,000/ μ L. At that time, bone marrow examination showed normal maturation of all cell lines with blasts. The patient gradually became ill because of congestive heart failure. At the age of 2 months, he died of bleeding from a duodenal ulcer. His WBC count was 31,700/ μ L with 11% blasts, 14% segmented neutrophils, 30% eosinophils, 2% basophils, and others one day before death. Autopsy findings showed marked extramedullary hemopoiesis of all cell lines in the liver.

MATERIALS AND METHODS

Cells. Peripheral blood mononuclear cells were separated by Ficoll-Paque (Pharmacia Fine Chemicals, Uppsala, Sweden) density centrifugation; the interface cells were harvested and washed twice in Iscove's modified Dulbecco's medium (IMDM, GIBCO, Grand Island, NY).

Cell culture. Liquid culture was carried out as follows: Cells were suspended in IMDM with 5% phytohemagglutinin-stimulated leukocyte conditioned medium (PHA-LCM) and 10% fetal calf serum (FCS) or the patient's platelet-poor plasma (PPP) or a healthy donor's PPP. The cells were incubated at 1×10^5 /mL in 25-cm² tissue culture flasks (Corning Glass Works, Corning, NY) or in 96-well tissue culture plates (Sumitomo Bakelite Co, Tokyo) at 37 °C in a humidified atmosphere of 5% CO₂ in air. Half of the culture medium was replaced once or twice a week with freshly prepared medium.

Methylcellulose culture was performed in 35-mm nontissue culture dishes (Falcon Labware, Oxnard, CA). A 1-mL mixture of 10^3 peripheral blood mononuclear cells, IMDM, 1.2% methylcellulose

(Dow Chemical Co, Midland, MI), 30% PPP, 1% bovine serum albumin (Sigma Chemical Co, St Louis), 1 unit of erythropoietin (Toyobo, Osaka, Japan), and 5% PHA-LCM or 5% GM-CSF was incubated at 37 °C in a humidified atmosphere of 5% CO₂ in air. PHA-LCM was prepared as described previously.⁹ Recombinant GM-CSF was generously provided by Dr K. Arai in DNAX.¹⁰ Using an inverted microscope, the culture plates were evaluated after 10 days for GM colonies, erythroid bursts, and mixed colonies.

Culture of single cells. The technique for single-cell manipulation was basically similar to that described previously.¹¹ Mononuclear cells were plated on methylcellulose medium at a concentration of 10³ cells/mL in a 35-mm culture dish. The transfer of a single cell to a second 35-mm culture dish containing 1 mL methylcellulose medium with 30% PPP, 5% PHA-LCM, and 1 U/mL of erythropoietin was accomplished under direct microscopic visualization by using a fine Pasteur pipette attached to a micromanipulator (Narishige Scientific Instrument Laboratory, Tokyo). After confirmation that a cell was present in each culture dish, incubation was carried out at 37 °C in an atmosphere of 5% CO₂ in air. On days 11 through 13 of incubation when the colonies appeared to have matured, individual colonies were lifted from the methylcellulose medium using a 3 µL Eppendorf pipette. The samples were spun in a Shandon Cytospin (Shandon Southern Products, Sewickley, PA) and stained with May-Grünwald-Giemsa.

Cytochemical studies. The cells were stained with peroxidase, Sudan black, alkaline phosphatase, toluidine blue, and periodic acid-Schiff (PAS) staining. Nonspecific esterase and chloroacetate esterase staining was performed according to Yam et al.¹²

Immunological studies. Reactivity of the fresh peripheral mononuclear cells and the cultures cells with murine monoclonal antibodies (My 4, 7, 8, Mo 1, Ia and Leu 2, 3, 4, 11, 12, J5) was assayed by an indirect immunofluorescence technique using a fluorescence-activated cell sorter.

Gene rearrangement studies. The status of the immunoglobulin heavy-chain genes and T cell receptor genes was assessed. DNA from blast cells was extracted, digested with restriction enzymes, size fractionated on agarose gels, Southern blotted, and hybridized with the human J_H immunoglobulin gene probe and the human T_β receptor gene probe.

Electron microscopy. Buffy coat cells of peripheral blood and cultured cells were fixed with glutaraldehyde and osmium tetroxide, dehydrated, and embedded in epoxy resin for transmission electron microscopy.

Chromosome analysis. Chromosomes were studied on samples of fresh peripheral blood cells with or without the stimulation of PHA and single colonies according to a method described previously.¹³

RESULTS

Liquid culture. Mononuclear cells isolated from the peripheral blood by Ficoll-Paque density centrifugation showed 86% blast cells. The blast cells had no granules and an undifferentiated appearance on light and electron microscopic examination (Fig 1). Mononuclear cells were cultured in the presence of 5% PHA-LCM and 1 U/mL erythropoietin with 10% PPP or 10% FCS. The total number of cells increased to 100-fold within ten days (Fig 2). The patient's PPP or healthy donor's PPP supported cell growth better than FCS. There was no significant difference between the patient's PPP and healthy donor's PPP. The blast cells had no characteristic cytochemical findings. All surface markers tested were negative. The immunoglobulin heavy-chain

genes and T cell receptor genes of the blast cells were found to be in germ line configuration. However, the cultured cells were positive in peroxidase, Sudan black, alkaline phosphatase, PAS, nonspecific esterase, chloroacetate esterase, and toluidine blue stainings. The cultured cells were reactive with My 7 (antibody-defining antigens expressed on cells in the myeloid lineage) but were not reactive with antibodies of My 4, Mo 1 or Ia. Smears of the cells obtained in a 9-day culture stained with May-Grünwald-Giemsa showed neutrophils, eosinophils, basophils, macrophages, erythrocytes, and megakaryocytes. Electron microscopic studies confirmed these cell lineages.

Methylcellulose culture. We observed a 50% plating efficiency in cultures of patient's peripheral blood mononuclear cells in the medium containing healthy donor's PPP in the presence of PHA-LCM and erythropoietin. The plating efficiency was extremely high when compared with that in cultures of cord blood mononuclear cells (Table 1). Many GM colonies, erythroid bursts, and mixed hemopoietic colonies were observed on the tenth day of culture. The GM

Fig 2. Time course of proliferation of peripheral blood mononuclear cells, 86% of which are blast cells. The total number of cells supplemented with healthy donor's PPP (●—●), patient's ppp (▲—▲) or FCS (■—■) is plotted on an exponential scale.

Table 1. In Vitro Methylcellulose Culture of Mononuclear Cells From the Peripheral Blood of the Patient With Myeloproliferative Disorder and Normal Cord Blood

	Media*	GM Colonies	Erythroid Bursts	Mixed Colonies
Patient	FCS	125 ± 10	17 ± 3	0
	PPP	455 ± 35	10 ± 1	5 ± 5
Cord blood	FCS	6 ± 2	5 ± 1	1 ± 1
	PPP	5 ± 1	3 ± 1	0

Peripheral mononuclear cells were plated at a concentration of 1×10^3 per dish in the presence of 5% PHA-LCM. The colonies were counted on day 10 of culture.

*Media contain 30% FCS or 30% healthy donor's PPP.

colonies consisted mainly of neutrophils, eosinophils, and basophils. Recombinant GM-CSF supported neutrophils, eosinophils, and macrophages but not typical basophils. We examined the cell lineage of constituent cells in colonies grown in a dish containing PHA-LCM or recombinant GM-CSF. About 50% of the cells grown in recombinant GM-CSF contained large granules that were toluidine blue-negative, whereas 50% of the cells grown in PHA-LCM were basophils that were toluidine blue-positive (Table 2). Electron microscopically, the typical basophils grown in PHA-LCM were polymorphonuclear and displayed membrane-bound cytoplasmic granules filled with fine particles (Fig 3A). These ultrastructural features were identical to those observed in human peripheral blood basophils. On the other hand, the cells grown in recombinant GM-CSF lacked the granules with a fine particulated structure but contained large granules that resembled those in young basophils grown in cord blood cell cultures (Fig 3B).¹⁴ We studied

Table 2. Differential Counts of Pooled Colonies in a Dish Containing PHA-LCM or Recombinant GM-CSF

	Differential Counts (%)				Undefined Cells*
	n	m	e	b	
PHA-LCM	52.0	2.0	6.8	39.2	—
Recombinant GM-CSF	44.8	1.6	4.0	—	49.6

Mononuclear cells (1×10^3 /mL) were cultured in the presence of 5% PHA-LCM or 5% recombinant GM-CSF. Differential counting was carried out on 250 cells from ten days of culture.

*Cells containing large granules that were negative for toluidine blue staining.

colony formation without PHA-LCM, and no colony formation was seen at a concentration of 10^3 cells per dish.

Single-cell culture. To establish the clonality of the colony, we cultured single cells that were transferred using a micromanipulator. Single-cell culture was done in a total of 136 cultures, of which 78 showed colony growth (57%). A total of 66 cultures gave evaluable data. May-Grünwald-Giemsa staining of the colonies revealed various types of colonies as shown in Table 3. Among them, 54 colonies (81.8%) contained basophils, 40 (60.6%) contained neutrophils, 40 (60.6%) contained eosinophils, and 25 (37.9%) contained macrophages. Three colonies contained erythrocytes. Twenty colonies consisted of less than 50 cells. The remaining 47 colonies were larger, and 34 colonies consisted of 200 to 3,500 cells. The appearance of a mixed colony consisting of five lineages derived from a single blast is shown in Fig 4A. The colony showed a compact red center and small

Fig 3. (A) Ultrastructure of mature basophil cultured for nine days in the presence of PHA-LCM. The nucleus is multilobulated. The granules exhibit a fine particulated content, which is typical of basophils in vivo (original magnification $\times 11,200$; current magnification $\times 8,176$). A detailed structure of the granules is highlighted in the inset (original magnification $\times 32,600$; current magnification $\times 23,798$). (B) Ultrastructure of toluidine blue-negative cell grown in the presence of recombinant GM-CSF. The dispersed chromatin of the nucleus indicates the cell is immature. The large granules with homogenous materials in the center are similar to those of basophil/mast cells grown in the culture of cord blood cells (original magnification $\times 11,200$; current magnification $\times 8,176$). A detailed structure of the granules is highlighted in the inset (original magnification $\times 35,700$; current magnification $\times 26,061$).

refractile cells in the surrounding region. Figures 4B and 4C show that the cells consisted of the mixed colony stained with May-Grünwald-Giemsa.

Chromosome analysis. The peripheral blood lymphocytes showed trisomy 21. The sample from peripheral blood without PHA stimulation showed trisomy 21 in all 28 metaphases examined. Of 13 colonies examined, eight colonies contained analyzable metaphases. Each colony contained 1 to 19 metaphases, yielding 55, and all of them were trisomy 21.

DISCUSSION

The hematologic state in the congenital myeloproliferative disorder of Down's syndrome is characterized by increased blast cells and resembles acute congenital leukemia. However, this disorder is unique in that the hematologic abnormality is self-limited. The work of Miller et al¹⁵ and our case show the coexistence of marked thrombocytopenia and a large number of blast cells. This hematologic profile is distinguishable from such myeloproliferative disorders in adults as chronic myelocytic leukemia and essential thrombocytopenia.

An important question in clarifying the characteristics of the blast cells in transient myeloproliferative disorder in Down's syndrome is whether such cells are leukemic or nonleukemic. Leukemia is defined as the clonal proliferation of abnormal cells that are transformed from hemopoietic cells. In our patient, it is difficult to determine whether this disorder is clonal hemopathy or not because there were no additional chromosomal abnormalities or genetic markers. However, it is certain that these blast cells are derived from the cells with trisomy 21 because even in phenotypically normal neonates showing abnormal hemopoietic states, chromosome studies revealed trisomy 21 mosaicism.^{3-6,16} In par-

Fig 4. (A) A multilineage colony derived from a single blast cell. The center is compact with small red cells. (B) May-Grünwald-Giemsa preparation of cells from the multilineage colony shown in (A). Erythroblasts are shown. (C) May-Grünwald-Giemsa preparation of cells from the multilineage colony shown in (A). Mature neutrophils and a young myeloid cell are shown.

ticular, Weinberg et al reported a neonate with this disorder having a 46,XX/47,XX,+21 karyotype limited to the hemopoietic system.⁵

The in vitro colony formation was reported to be normal in transient myeloproliferative disorder¹⁷ or transient acute leukemia in Down's syndrome.¹⁸ However, the relationship between blast cells and colony-forming cells is unclear. We demonstrated that blast cells in our patient could proliferate to form large colonies and differentiate into various kinds of cell lineages. The lack of a significant difference between the

patient's plasma and healthy donor's plasma for supporting cell growth suggested that there were no abnormalities of hemopoietic regulators. The single-cell transfer experiment demonstrated that about half of the blast cells were colony-forming cells that could proliferate and differentiate into basophils, neutrophils, eosinophils, macrophages and erythrocytes. Electron microscopy showed the maturation of and differentiation into each lineage.

Nakahata and Ogawa¹⁹ reported a human blast colony assay. However, the replating efficiency of these cells is not as high as those of murine blast colonies.²⁰ The treatment with monoclonal antibody (MY-10) is necessary for the enrichment of stem cells.²¹ The mononuclear fraction of peripheral blood in this patient has an extremely high plating efficiency and differentiation activity. The predominance of colonies containing basophils provided an opportunity for studying whether recombinant GM-CSF supports the differentiation of basophils in addition to neutrophils, eosinophils, and macrophages.¹⁰ It is suggested that recombinant GM-CSF does not support the differentiation of basophils and that other factor(s) might be required for the terminal maturation of basophils.

In acute myelogenous leukemia, the in vitro colony formation was reported to be abnormal; large numbers of small

colonies or clusters were formed, and the constituent cells remained immature.^{22,23} We previously showed that megakaryoblastic leukemic cells also have the capacity for differentiation into some lineages that are not expressed in vivo.⁹ However, in the present case, the findings of the cell differentiation of blast cells into various kinds of cells in vitro were in agreement with the findings of neutrophilia, eosinophilia, basophilia, and thrombocytopenia in vivo.

Before the patient died, granulocytosis developed concurrent with a decrease in the number of blast cells. Autopsy findings revealed extramedullary hemopoiesis in the liver, but the infiltration of blast cells was not marked. In view of the in vitro and in vivo findings, hemopoietic differentiation was not blocked. Therefore, it is assumed that the blast cells of this patient with transient myeloproliferative disorder are transformed from hemopoietic stem cells with trisomy 21 and that these clones could not survive persistently due to their high differentiation activity.

ACKNOWLEDGMENT

We thank Dr T. Ishizuka, Dokkyo University School of Medicine, for the autopsy findings. We also thank Dr H. Hirai, Tokyo University of Tokyo, for the examination of gene rearrangement.

Relationship of the Hematopoietic Cycle to the Combined Activities of a Stimulator and a Short-Lived Inhibitor

By Philip J. Burke and Judith E. Karp

Substances that circulate in the blood following drug-induced bone marrow aplasia produce a biphasic curve of DNA synthesis in cells in liquid and semisolid cultures which reflect relative concentrations of these growth regulators of hematopoiesis. This net effect magnified by induced marrow failure in human, rat, and mouse is a sinusoidal curve that is the reciprocal of the WBC. Generated in the bone marrow, humoral stimulating activity (HSA) produces peak growth of colonies in agar (CFU-GM) during the proliferative phase of bone marrow recovery, whereas humoral inhibitory activity (HIA), present at the time of marrow maturation, suppresses colony growth. Split femurs from rats given cyclophosphamide (CY) and killed at regular intervals condition media that affect DNA synthesis in a fashion similar to that of HSA-HIA in the rats' sera. In Dexter cultures, HSA is derived from the adherent

rather than the hematopoietic cell, whereas HIA is produced by that nonadherent cell. Animals treated with a lethal dose of busulfan (BU) produce large amounts of HSA in vivo until death. Those transplanted with adherent bone marrow cells depleted of hematopoietic cells on day 1 after BU also die, whereas those given nonadherent marrow cells survive and generate HIA at the time of bone marrow recovery. HSA and media conditioned by bone marrow stromal cells causes an increase in spleen colonies (CFU-S), as does HIA. These studies support the contention that the net effect of putative regulators of hematopoiesis, measured in the drug-perturbed state, consist of a constantly present stimulator emanating from bone marrow stroma, and a variable inhibitor produced by maturing hematopoietic bone marrow cells.

© 1987 by Grune & Stratton, Inc.

NORMAL PERIODIC oscillations of the formed elements in the peripheral blood suggest that hematopoiesis is regulated by positive and negative humoral mechanisms.¹ Support for this concept derives from the findings of Bierman² and Morley and colleagues³ of growth-stimulating factors in sera during induced pancytopenia. With an assay capable of measuring the negative phase of a sine-wave, we can detect both stimulatory and inhibitory activities in the sera of patients recovering from drug-induced sublethal bone marrow aplasia.⁴ Sequential studies designed to elucidate this phenomenon yielded data that can now be integrated with emerging evidence for the presence of characterized substances that influence the growth of hematopoietic cells in the bone marrow.⁵

The observed consistent fluctuation of humoral factors during induced acute failure and subsequent recovery of hematopoiesis is best explained by the net activity of a stimulator of constant amount originating in the bone marrow stroma, coupled with an inhibitor of varying concentration derived from maturing hematopoietic bone marrow elements. The result of this interaction is bone marrow homeostasis.

MATERIALS AND METHODS

Mice. Female CD₂-F₁ (BALB/c × DBA/2) mice, aged 9 to 11 weeks and weighing ~20 g, were obtained from M. A. Bioproducts, Bethesda, MD and used within 6 weeks of arrival. They were housed ten to a cage and were given chlorinated tap water and Purina Laboratory Chow ad libitum. In three separate experiments, 30 mice per point received cyclophosphamide (CY), 300 mg/kg (LD₅) intraperitoneally (IP), or saline. The results of the three experiments were similar, and the data were combined for presentation (analysis of variance).

Rats. Female LBN-F₁ (Lew × BN) rats, aged 9 to 12 weeks, were obtained from Harlan Sprague Dawley and used within 6 weeks of arrival. They were kept four to a cage and were given Purina Rat Chow and water ad libitum.

In three separate experiments, nine rats per point received CY, 175 mg/kg (LD₅) IP. To determine the timing of the appearance and magnitude of HSA after cytosine arabinoside (ara-C), rats received a single course of drug at high dose to induce total bone

marrow aplasia, followed by recovery of formed elements over time. Triplicate animals were exsanguinated daily, and HSA, HIA, and WBC count were determined.

Humans. In initial trials, 12, and in subsequent trials, a further 20 adult patients who had progressive incurable neoplasms but no detectable physiological defects and whose hematopoietic function was adjudged normal by peripheral blood examination and bone marrow biopsy and aspirate were treated with CY, 120 mg/kg intravenously (IV). The effect on DNA synthesis of the pretreatment sera of each was within normal range. All patients were advised of procedures and attendant risks, in accordance with institutional guidelines, and gave informed consent.

Sera collection. Mouse blood was obtained by exsanguination from replicate animals daily until WBC recovery after therapy. Rat blood was obtained in a similar fashion under metaphane anesthesia. Prior to therapy and three times a week until the peripheral WBC count stabilized, 10 mL of human whole blood were collected from each patient and allowed to clot. All sera were separated and stored immediately at -70 °C. At the end of the collection period, all sera were assayed simultaneously to determine the effect of the sequential sera on [³H]TdR incorporation by bone marrow cells in the assay system. Normal sera were obtained from 30 volunteers and pooled. When these 30 normal sera were assayed individually for their effects on ³H-thymidine [³H]TdR incorporation by bone marrow cells, each fell within the range of 1 SEM of the activity of the pool. The activity present in pretreatment and posttreatment sera of all species was compared with the activity of the normal control pool in each assay and reported as a percentage of normal.

Scintillation assay. The effect of sera on [^3H]TdR incorporation by normal rodent bone marrow cells was measured by the scintillation counting technique. Control studies in the laboratory have demonstrated that the sum of activities of distinct stimulatory and inhibitory humoral factors that influence cell proliferation is measurable by this method (ref 6, unpublished control observations, July, 1972).

In these assays, 1.0 $\mu\text{Ci/mL}$ of culture of [^3H]TdR (specific activity, 1.9 Ci/mmol) was added to tubes in triplicate of RPMI 1640 medium and incubated with fresh bone marrow cells ($10^6/\text{mL}$) at 37°C in a 7% CO_2 -humidified atmosphere at a final volume of 2 mL. Sera to be evaluated were added to attain a concentration of 30%. After 18 hours of incubation, the cultures were terminated by immersion in ice, and the cellular contents of each tube were collected under vacuum on a glass-fiber filter. Each tube was washed with cold 0.9% NaCl solution, and the wash was added to the filter. Following three washings with 0.9% NaCl solution, the acid-insoluble materials on the filter were precipitated by three washings with cold 5% trichloroacetic acid and were then washed three times with absolute ethanol. The dry filter was transferred to a screw-top vial to which 6 mL of scintillation fluid was added, cooled, and counted in a liquid scintillation spectrometer. Results are expressed as actual counts per minute for each experiment.

Preparation of [^3H]TdR microautoradiographs. Aliquots of rodent femur and aspirated human bone marrow tumor cells were prepared and analyzed for labeling index (LI) by methods described previously.⁴

Aplasia model. In studies in the model of lethal bone marrow aplasia, groups of rats were given an ablative dose of BU, 35 mg/kg IP on day 0. If not rescued with syngeneic normal bone marrow, all animals died by day 13 with signs and symptoms of bone marrow failure.⁷ In syngeneic transplant experiments, normal femur bone marrow cells were incubated at 37°C in RPMI 1640 media with 15% autologous sera at a concentration of $5 \times 10^5/\text{mL}$ at a 6-mL vol (30×10^6) in each 25-cm² Falcon TC flask, with eight flasks per point. After incubation for 2 hours, the total supernate with nonadherent cells was aspirated, the cells washed in RPMI media, and the total cells were injected IV into a single animal, 8 per group, on day 1 after BU. Similarly, each animal from another group of eight received the total adherent cells contained in the flask after removal by gentle agitation and scraping with a rubber policeman. Similar numbers of control animals received RPMI-1640 cultured media. Following injection, each animal was followed with assay of WBC, HIA, and HSA. Animals that survived were observed for 100 days before being killed.

Agar assay for CFU-GM. Cell suspensions from normal rat femurs were cultured at a final concentration of 1×10^5 cells in quadruplicate 35 $\times$ 10-mm Falcon Petri TC dishes in 1 mL of 0.3% Difco-Bacto and Dulbecco's minimal essential medium (DMEM) supplemented with penicillin, streptomycin, glutamine, asparagine, and 15% normal rat serum, or replicate sera obtained before, during, and after treatment at daily intervals from groups of drug-treated rats. Agar cultures were maintained at 37°C in a humidified atmosphere containing 7% CO_2 and scored for number of colonies (>40 cells) on day 7. All colonies were removed from each agar plate by gentle capillary pipetting, transferred to glass slides, and stained with 0.5% orcein, buffered Wright's stain, and myeloperoxidase to evaluate the cell types present in individual colonies. Comparison of numbers of colonies in pretreatment sera and in sera throughout marrow recovery was made by Student's *t* test and the Wilcoxon rank sum test.

Long-term stroma cultures. Split femurs, obtained on day 8 after rats were treated with a lethal dose of BU, 35 mg/kg, were cultured in replicate in 25-cm² Falcon TC flasks with 15% normal rat sera and 85% DMEM in conditions similar to the agar assay,

with weekly partial decanting of supernate and refeeding. Supernates were sterilized through a 0.22- μm filter and frozen at -70°C until assayed simultaneously for DNA synthesis in rat bone marrow cells.

Short-term conditioned media. Replicate femurs harvested at 2-day intervals from rats treated with CY, 175 mg/kg, were split longitudinally with a scalpel and cultured in 5% normal rat sera and 85% DMEM in 25-cm² Falcon TC flasks at 37°C in 7% CO_2 at a volume of 10 mL. During 3 successive days, four cultures were terminated daily, the conditioned supernate (HSA-CM) was sterilized through a 0.22- μm filter, and the cultures were frozen for later simultaneous analysis for DNA stimulatory activity in the 18-hour scintillation and CFU-c assay.

Endotoxin screening. All sera and conditioned media used in these experiments were determined to be free of endotoxin by the limulus amoebocyte lysate assay.

Spleen colony assay. CFU-S were assayed by the method of Comas and Byrd,⁸ with the modification that assay rats received total body irradiation at a total of 900 rad split equally at hour 1 and hour 6 and delivered at a dose rate of 116 ± 3 rads/minute from a ^{136}Cs -Gammacell 40 radiation source.

Stem cell suicide assays. In growth stimulation assays and suicide experiments, replicate cultures were established in Dulbecco's minima essential medium (DMEM) at a concentration of marrow cells $5 \times 10^5/\text{mL}$ and incubated for 17 hours with either normal sera, HSA, or HIA, [^3H]TdR, (85 $\mu\text{Ci/mL}$; specific activity, 20 Ci/mmol) added for the last 1 hour of the 18-hour cultures. The cultures were then washed three times with cold thymidine solution (0.8 mmol/L), washed three times with media, and then each of eight replicate cultures was injected intravenously (IV) in animals on day 1 after irradiation. Cells cultured in DMEM with specific sera without suicide drugs and handled similarly served as controls in these studies.

Statistical analysis. Data were analyzed using Student's *t* test to compare control groups with suicide groups, analysis of variance to determine if groups could be combined, SE to evaluate percentage of kill by the method of Lord and colleagues⁹ for the in vitro and in vivo CFU-S assays, and the Wilcoxon rank sum test to compare DNA synthesis over time.

RESULTS

Correlation of bone marrow recovery and humoral factor kinetics after drug-induced aplasia. Bone marrow cells and sera were obtained sequentially through aplasia and recovery from 12 patients with normal hematopoiesis who received CY, 120 mg/kg over 48 hours (Fig 1). The LI of the granulocyte precursor compartment (myeloblasts, progranulocytes and myelocytes; proliferative pool, Pro) increased significantly in all, with the mean peak LI detected on day 9 following CY (200% of pretreatment values), then fell to less than pretreatment levels (75%) by day 25 at the time of bone marrow maturation [metamyelocytes, bands, polymorphonuclear lymphocytes (PMNs); nonproliferative, NonPro].

The growth activity of the Pro paralleled the presence of HSA, which achieved peak values of 200% of pretreatment sera on day 10, then declined to a nadir on day 20 (50%). This decay of HSA and increasing HIA was associated with a decrease in bone marrow proliferative activity occurring at the time of metamyelocyte differentiation, 5 days before granulocyte release and 12 days before recovery of normal levels of WBC.

Comparison of hematopoietic recovery and HSA induction after drug-induced bone marrow aplasia in three spe-

Fig 1. The mean WBC count (●), labeling index (▲), and effect of sequentially obtained sera on 18-hour normal bone marrow $[^3\text{H}]$ -thymidine ($[^3\text{H}]\text{TdR}$) incorporation (○) from 12 patients treated with cyclophosphamide (CY), 120 mg/kg. Vertical bars represent ± 1 SEM.

cies. Absolute bone marrow aplasia was induced in three species (mouse, rat, human) by a single comparable dose of CY, and the temporal relationship of hematopoietic recovery and HSA induction was monitored in each and compared (Fig 2). Sequential sera were collected daily from $\text{CD}_2\text{-F}_1$ mice (30/point) that had received CY 300 mg/kg IP (LD_{50}), from LBN rats (9/point) that had been given CY 175 mg/kg IP (LD_{50}), and sequentially from 20 patients with malignancy but with normal bone marrows who had received CY 120 mg/kg IV on day 0 of therapy. The effect of these serial sera on $[^3\text{H}]\text{TdR}$ incorporation into the DNA of autologous bone marrow cells was measured in vitro in simultaneous replicate cultures, and the results were expressed as the mean percentage of their respective day 0 control value ± 1 SEM (Fig 2).

These data demonstrated the temporal relationship of bone marrow regeneration and associated peak detection of

Fig 2. Correlation of humoral stimulating activity (HSA) and hematopoietic recovery time after cyclophosphamide (CY)-induced aplasia in mouse, rat, and human. All animals received comparable doses of CY. After an initial fall in activity, HSA reached maximum levels on day 3 in mouse (●), day 6 in rat (○), and day 9 in human (▲), then fell to levels below pretreatment. These oscillations were the reciprocal of the WBC count.

HSA and HIA induction following bone marrow aplasia induced by a single comparable dose of drug in the three species. The ratio was 1:2:3 in mouse, rat, and human, respectively.

Serum mixing experiments. To determine the relative growth promoting activity present in the sera, pools of HIA, HSA, and normal sera were mixed at various concentrations and assayed using normal marrow cells (Fig 3). Normal sera at 30% supported growth well, whereas concentrations as low as 5% HIA or HSA mixed with normal sera produced a significant effect on DNA synthesis. When HIA and HSA were mixed in equal proportions, the activity produced equaled that of normal sera. The lines were constructed by best-fit analysis.

Correlation of HSA and degree of aplasia. Rats were given incremental amounts of drugs to maximally tolerated doses: CY, 25 to 200 mg/kg IP; ara-C, 50 to 400 mg/kg every 8 hours $\times 6$ subcutaneously; and BU, 5 to 30 mg/kg IP (Fig 4). There was a linear relationship of drug dose and the effect of sera obtained on day 6 after each drug on DNA synthesis of cultured bone marrow cells. The peak quantity of HSA induced related directly to the dose of drug and resultant amount of bone marrow depression.

Source of humoral factors: media conditioned by bones. Aliquots of the cell-free conditioned media (CM) taken daily for 3 days from the 24-, 48-, and 72-hour cultures of split femurs from replicate rats killed at 2-day intervals after treatment with CY, 175 mg/kg, demonstrated an effect in the DNA scintillation assay that paralleled the measured HSA in sera. Day 4 femurs containing early recovery proliferative phase bone marrow elements, as measured by a rising LI and progranulocytic morphology, elaborated factors over 3 days which promoted DNA synthesis that was 155% greater than that of normal bones (Fig 5). Bones harvested on day 6 of CY and established in culture produced increasing amounts of HIA, with subnormal DNA synthesis induced by the 72-hour CM. In the experiment carried through the period of bone marrow recovery and "hypermaturation," the media from bones cultured on day 10 at the time of WBC recovery and granulocytosis markedly depressed DNA synthesis, reflecting the presence of HIA. At the time of reestablished bone marrow homeostasis, media conditioned by femurs from treated animals, which then contained

Fig 3. Effect on DNA synthesis in normal bone marrow cells of mixing normal sera with phosphate-buffered saline (PBS) (●), humoral stimulating activity (HSA) (○), humoral inhibitory activity (HIA) (□), and HSA with HIA (▲), in various proportions. The final concentration of serum is 30%. Vertical lines are ± 1 SEM.

Fig 4. The dose-response of humoral stimulating activity (HSA). The quantity of HSA induced by incremental doses of the bone marrow suppressing drugs cyclophosphamide (CY) (Δ), cytosine arabinoside (ara-C) ($\square$), and busulfan (BU) ($\bullet$) is linear, as measured by the effect of sera on DNA synthesis in normal bone marrow.

normal marrow elements and cellularity, influenced DNA synthesis in a manner similar to that of normal controls. The curves of DNA synthesis generated by these CM correlated directly with the DNA synthesis induced by the serum obtained on day 1 of each culture set.

These results demonstrate that femurs obtained during aplasia and subsequent recovery elaborate soluble substance(s) during 72-hour culture that stimulate and inhibit DNA synthesis. Concomitantly, similar humoral activities are detected in autologous sera, suggesting that the source of these serum factors is likely bone and/or bone marrow cells.

Stimulatory media conditioned by long-term stromal cultures. Stromal cells from marrows of rats lethally treated with BU were established in culture (Fig 6). Adherent cells grew to a confluent monolayer in 2 to 3 weeks and supported the growth of increasing numbers of sessile, round cell colonies on stalks containing macrophages and monocytes. CM from replicate flasks cultured with 15% normal sera in two experiments stimulated the growth of hematopoietic cells to 120%, 163%, and 147% above normal serum on days 7, 14, and 21, respectively. Replicate cultures maintained through week 9 continued to condition media to stimulatory levels >130% of control media and sera. Cultures of normal bone marrow adherent cells, with nonadherent cells removed, stimulated growth of hematopoietic cells to 130% of normal by day 14 of culture (Fig 6).

These data demonstrate the viability of stromal cells after in vivo lethal doses of BU, the production of HSA by such

Fig 5. The conditioning of media by femurs of cyclophosphamide (CY)-treated rats. Femurs harvested from animals before treatment and when recovering from drug-induced aplasia, and cultured at 2-day intervals produced conditioned media ($\bullet$, $\blacksquare$) both stimulated and inhibited DNA synthesis in a similar fashion to sera ($\circ$) obtained sequentially from the same rats. Vertical bars are ± 1 SEM.

Fig 6. Stimulation of hematopoietic cell proliferation by media conditioned by stromal cells from busulfan (BU)-treated rats. Supernates from stromal cultures were decanted weekly and assayed for DNA synthesis stimulation in marrow hematopoietic cells ($\bullet$) and compared with those in simultaneous cultures without cells (-----). Bars ($\pm$) are the SEM of two experiments; Δ indicates the stimulation induced by conditioned media from normal bone marrow adherent cells depleted of hematopoietic cells, assayed at 2 weeks. Solid line, degree of confluency of the growing monolayer of cells; dotted line, cellularity of the epithelial, mononuclear, and adipose cell colonies growing as sessile pedunculated pods on the monolayer.

cells, and the ability of normal stroma depleted of nonadherent hematopoietic cells to produce HSA.

BU model of aplasia. The lethal bone marrow ablation induced by >24 mg/kg of BU in the rat and the amelioration of that aplasia with infused syngeneic bone marrow cells⁷ provides a useful model to study mechanisms of hematopoietic reconstitution (Fig 7). A series of experiments involving bone marrow rescue to relate dose and source of cells with restoration of bone marrow function and production of HSA and HIA was conducted. In this model of aplastic anemia, HSA increases linearly to maximal levels at the time of most profound aplasia prior to the death of the animal from the sequelae of bone marrow failure. In the studies reported here, 250 rats were given BU, 35 mg/kg on day 0. Twenty-four hours after BU, each of one-third of the animals received IV

Fig 7. Busulfan (BU) model of bone marrow aplasia and rescue. Groups of eight animals received BU 35 mg/kg intraperitoneally on day 0. Four animals in each group were given 30×10^6 autologous nonadherent bone marrow cells intravenously on day 1 (BMR+); the remainder received media alone (BMR-). WBCs (Δ) and humoral stimulating activity (HSA) ($\circ$) of the BMR+ were contrasted with the WBCs ($\blacktriangle$) and HSA ($\bullet$) of the BMR- animals. All BMR- animals died by day 13, whereas those rescued survived and were killed at 100 days. Engraftment of donated autologous nonadherent bone marrow cells was associated with a decline in HSA as the bone marrow matured.

Fig 1. The mean WBC count (●), LI (▲), and effect of sequentially obtained sera on 18-hour normal bone marrow [^3H]-thymidine [^3H]TdR incorporation (○) from 12 patients treated with cyclophosphamide (CY), 120 mg/kg. Vertical bars represent ± 1 SEM.

cies. cells, and the ability of normal stroma depleted of nonadherent hematopoietic cells to produce HSA.

BU model of aplasia. The lethal bone marrow ablation induced by >24 mg/kg of BU in the rat and the amelioration of that aplasia with infused syngeneic bone marrow cells⁷ provides a useful model to study mechanisms of hematopoietic reconstitution (Fig 7). A series of experiments involving bone marrow rescue to relate dose and source of cells with restoration of bone marrow function and production of HSA and HIA was conducted. In this model of aplastic anemia, HSA increases linearly to maximal levels at the time of most profound aplasia prior to the death of the animal from the sequelae of bone marrow failure. In the studies reported here, 250 rats were given BU, 35 mg/kg on day 0. Twenty-four hours after BU, each of one-third of the animals received IV

Fig 7. Busulfan (BU) model of bone marrow aplasia and rescue. Groups of eight animals received BU 35 mg/kg intraperitoneally on day 0. Four animals in each group were given 30×10^6 autologous nonadherent bone marrow cells intravenously on day 1 (BMR+); the remainder received media alone (BMR-). WBCs (Δ) and humoral stimulating activity (HSA) (●) of the BMR+ were contrasted with the WBCs (Δ) and HSA (●) of the BMR- animals. All BMR- animals died by day 13, whereas those rescued survived and were killed at 100 days. Engraftment of donated autologous nonadherent bone marrow cells was associated with a decline in HSA as the bone marrow matured.

Fig 8. Effect of sequential sera obtained before and after cytosine arabinoside (ara-C), 200 mg/kg every 8 hours $\times$ 6 on bone marrow CFU-GM (O—O). The growth is the reciprocal of the WBC count (●—●). Vertical lines are $\pm$ 1 SEM.

the total nonadherent autologous nucleated bone marrow cells from a single flask of replicate cultures initiated at 30×10^6 cells (bone marrow rescue, BMR+). Each animal in a second group received the total population of adherent cells from a single flask after depopulation of the nonadherent cells (BMR-). Each animal in a third group was given culture media. All were monitored for fluctuations of WBCs, and HSA and HIA were gathered every other day from four rats of each group. Granulocyte counts in all animals dropped rapidly to 0 by day 7, whereas the number of absolute lymphocytes fell to 25% of initial values.

HSA levels rose gradually in both BMR+ and BMR- groups to ranges between 175% and 200% of pretreatment values by day 7. The ultimate value prior to death in the BMR- group reached 210% on day 13. Net detectable HSA in BMR+ animals declined by day 9 as the bone marrow cellularity increased with all proliferative hematopoietic elements present and returned to pretreatment levels at the time of WBC recovery.

Bone marrow aspirates of the animals not given bone marrow support (BMR-) demonstrated marked bone marrow hypoplasia by day 7, and all animals were dead with hemorrhage and/or infection by day 13. In contrast, the WBCs in the BMR+ group began to recover by day 10 and

reached pretreatment counts by day 12 through 14. The cellular differential, primarily lymphocytes in the unperturbed state, now revealed granulocytes (75%) by day 13 following autologous rescue. These animals rescued from bone marrow aplasia survived until killed on day 100.

Effect of HSA and HIA on CFU-GM. Replicate normal LBN-F₁ rats given ara-C, 200 mg/kg every 8 hours $\times$ 6, were exsanguinated at intervals; their WBCs were counted, and the sera were stored. After WBC recovery from aplasia, the collected sera were plated at 15% in agar in replicate cultures containing 1×10^5 bone marrow cells, with cell concentrations and media similar to those routinely used in the 18-hour [³H]TdR assay of DNA synthesis. Colonies of >40 cells visible in four replicate dishes counted on day 7 of agar culture were identified as CFU-GM by peroxidase staining and morphology with Wright's stain. Pretreatment sera supported the growth of 28 ± 2 colonies, whereas no colonies were present in sera containing ara-C; 36 ± 3 colonies grew in sera obtained on day 6, and 41 ± 3 grew in sera of day 9 during the time of bone marrow aplasia and early recovery. Only 21 ± 2 colonies grew in sera collected at the time of WBC recovery and a mature bone marrow (Fig 8). These counts were within the range of linearity of this assay in our laboratory and differed significantly from each other ($P < .05$). Similar results were obtained in two subsequent experiments.

Effect of HSA and HIA on CFU-S. The results of 6 experiments, 3 with and 3 without [³H]TdR suicide, each experiment having 8 recipient rats for each sera in replicate cultures, were combined (analysis of variance) (Table 1). Normal bone marrow cells were cultured with normal sera, HSA, and HIA for 18 hours and were then injected into irradiated recipient rats, with quantitation of spleen colonies on day 8. In the six studies without a suicide component, HSA increased the number of colonies by 50% (Table 1, $P < .001$). Most unexpected was the stimulation of spleen colony formation by HIA, a reagent previously determined to be inhibitory to growth of hematopoietic cells in both the DNA scintillation and the CFU-GM assay. This paradoxical stimulatory action of HIA was confirmed in the [³H]TdR suicide experiments. Although the number of CFU-S was not significantly reduced by [³H]TdR in either normal or HSA cultures (10%), culture with HIA produced a significant reduction in total colonies formed (33%, $P < .005$), demonstrating that there had been movement of CFU-S cells into cycle in the presence of HIA.

Table 1. Effect of Humoral Regulators on Growth of Stem Cells

DISCUSSION

Periodicity of hematopoiesis. After drug ablation of cells in the proliferative phase of the bone marrow, the eventual depletion of the residual mature cells that prevent major fluctuation in circulating blood elements results in marrow aplasia and pancytopenia. With dissipation of these buffers, the oscillating forces that drive marrow reconstitution are readily measurable in the blood (Figs 1 and 2).

HSA, directly related to the rate of marrow regrowth, reaches maximal values at the time of full proliferation of regenerating cells. Subsequently, with the enlarging nonproliferative phase of marrow recovery, HIA becomes the dominant humoral regulator. Whether HSA and HIA act independently, are a summation of activities both local and distant from the bone marrow, are a spillover of excess amounts of locally acting forces, or are unrelated to hematopoiesis has been scrutinized.

These studies using sera as reagents are imprecise at best, since cytotoxic agents that induce marrow aplasia in the intact animal also damage other growing tissues. During the period of cell recovery, it is reasonable to assume that the blood contains myriad pleiotrophic and tissue-specific growth promoters mixed with synergistic proteins, likely multiple, that are responsible for the restoration of the cellular elements and microenvironment of the bone marrow. We lump these combined activities as HSA and HIA, likely pluripoiectins from multiple sources that reflect the global cytotoxic effects of drug and the summation of all regenerative forces active in the intact animal. The amplitude of HSA and HIA relates directly to the dose of drug and the resultant degree of aplasia induced, although the regeneration time of bone marrow recovery is unchanged and is species-specific.

Humoral regulators. Lord and co-workers and Wright and colleagues identified distinct local activities in the adherent layer of cultures of regenerating bone marrow that independently stimulate or inhibit hematopoiesis with a balanced oscillation,¹⁰⁻¹² whereas Frindel and colleagues defined the role of diffusible serum factors that regulate CFU-S growth and proliferation at a distance from their source of production.¹³⁻¹⁵ Complicating the interpretation of humoral data is the variable presence in serum of factors such as endotoxin^{16,17} that rapidly stimulate increased synthesis and release of colony-stimulating activity (CSA) by mononuclear cells.¹⁸

Stroma cultures derived from animals with hematopoiesis ablated by BU have morphology consistent with that described by Dexter and co-workers and Bentley and Foidart^{19,20} but do not produce CFU-C or CFU-S.^{7,21} This transplanted stroma produces HSA without inhibition (Fig 6), mimicking HSA kinetics as measured in the BU-treated rat unrescued by donated bone marrow (Fig 7). Verification that the stromal cell is the source of HSA comes from other laboratories as well.²²⁻²⁵ Cross-reactivity between HSA and mouse L cell colony-stimulating factor (CSF) has been demonstrated,²⁶ and it is likely that HSA is a composite of a number of CSFs and other cell- and tissue-specific substances. The relative decrease with marrow recovery may reflect down-regulation of active sites for CSA and not relate to an actual reduction of available stimulating factor.²⁷

During recovery from induced aplasia, HSA is balanced by HIA, the two producing a curve of equal duration and opposite direction and the reciprocal of the WBC. Bone marrow extracts of a short-acting inhibitory activity that block the entry of CFU-S into cycle^{28,29} may be produced by bone marrow macrophages.^{30,31} Candidates for this function are the glycoproteins lactoferrin (LF), transferrin (TF), acidic isoferitin (AIF),^{32,33} and type E prostaglandins (PGE II).³⁴⁻⁴⁰

Aplasia model. The BU model of lethal bone marrow aplasia serves as a bioassay for the effect of restoration of function on net humoral activities by selected infused cell populations separated from whole bone marrows (Fig 7). Sera obtained sequentially during the period of aplasia have increasing amounts of HSA, with peak activity at the time of profound aplasia prior to death. Such maximal levels of HSA have also been detected in patients with idiopathic aplastic anemia.⁴¹

Detectability of HSA in the BU model is countered by rescue of lethally treated rats with nonadherent cells obtained from short-term bone marrow cultures. These hematopoietic elements produce increasing HIA over time following injection until balanced bone marrow reconstitution occurs. In contrast, the infusion of adherent "stromal" cells alters neither the maximal level of stimulator nor the fatal outcome. HIA is derived from the nonadherent hematopoietic cells, occurs with engraftment and maturation of all formed elements of the rescue marrow, and is apparent before release of cells into the peripheral blood.

Effect on stem cells. The effects of stimulators and inhibitors from varied sources on bone marrow precursor cell growth and differentiation have been measured. The increased proliferation of CFU-S following treatment of mice with phenylhydrazine is accompanied by an increase in stimulator and a simultaneous decrease in inhibitor production. The two distinct factors¹⁰⁻¹² alternately block each other's synthesis in response to a signal for more or less production from the progenitor cell compartment⁴²—data supporting the theory that activities of short-range substances contained in the marrow locally regulate stem cell cycle.⁴³⁻⁴⁵ In contrast, investigating the cause of movement away from self-renewal to differentiation to committed stem cells, Guignon and colleagues and Sainteny and co-workers found that inhibitor production after treatment with ara-C channels stem cells into an altered erythroid-granulocytic balance^{46,47} by factors acting at a distance.⁴⁷⁻⁴⁹

In our progenitor cell cultures, HSA produced increased growth of stem cells. In addition, there was unexpected stimulation of growth of CFU-S by HIA, a reagent determined to be inhibitory to growth of hematopoietic cells in both the DNA scintillation and the CFU-GM assay. This paradoxical stimulatory action was confirmed in the [³H]TdR suicide experiments, with movement of CFU-S cells into cycle. These findings suggest that HIA is short-lived and that the HIA-containing sera obtained during bone marrow maturation contained maximal HSA as well. HSA is effectively blocked for the brief time of the other assay systems by the short-acting inhibitory substance in high concentration. Constantly available only in vivo, in 18-hour cultures un replenished HIA apparently disappears and HSA

acts unopposed. This result supports the concept of a long-lived stimulator whose constant presence is buffered and neutralized, as in the mixing experiments, by a short-acting local but powerful inhibitory factor that increases with maturation of hematopoietic elements in the bone marrow.

The growth effect of stimulators on CFU-S but their inconsistent movement into cell cycle^{50,51} suggests the presence of a pool of progenitor cells with a heterogeneous response to growth promotion v differentiation or with a random availability for growth promotion toward pluripotent cells. The [³H]TdR suicide experiments and our clinical experience with sequential therapy timed at maximal bone marrow regrowth⁵²⁻⁵⁵ offer little evidence for significant killing of CFU-S by cytotoxic cell cycle-dependent drugs in vitro. Either such drugs have little direct effect on stimulated stem cells²⁴ or the site of action of these poietins is a differentiated or committed and expendable subset of the pluripotent cell population.⁵⁶

Hematopoiesis model. The demonstration of a sine wave during marrow ablation and recovery is consistent with the concept of two long-range regulators of hematopoiesis^{51,57,59} and with the theory that postulates two distinct local and counter-balancing activities within the bone marrow (Fig 9).^{10,42} HIA fits the category of short-term and short-range inhibition, whereas HSA has long-term activity. Both are released into the peripheral blood. Although the data of Lord and colleagues^{43,44} support an ebb and flow of both HSA and HIA, with reciprocal activity, our results in the BU model with rescue suggest instead the presence of a constant stimulator of stromal source countered periodically by a short-lived locally acting inhibitor, elaborated by maturing hematopoietic elements. That HSA directly stimulates the stem cell pool as a long-range regulator is supported by our stem cell assays and by evidence from other laboratories as well that aplastic animals elaborate long-range humoral regulators of stem cell growth.⁶⁰

This model of perturbed hematopoiesis (Fig 9) is most consistent with data derived from our sequential studies. Administration of drug X effectively eliminates all cells in the bone marrow that are in cell cycle. As the residual mature bone marrow cells decrease, HSA, comprised of a number of glycoproteins with CSA capability, increases. Emanating from the stroma, unopposed HSA acts on quiescent stem cells which are capable of entering at random either a self-renewal mode or differentiation to committed progenitors. At maximum levels of HSA on day 8 through 10

Fig 9. Model of hematopoiesis.

after cytotoxic drug, the bone marrow is totally proliferative. HSA continues to be produced at a constant amount, but its net measurable amplitude decays as HIA, a short-acting but powerful inhibitor derived from bone marrow cells in the maturing hematopoietic compartment, interacts directly with HSA to counter its activity. As the maturation compartment enlarges and net inhibition ensues, mature elements are released into the peripheral blood while access from the stem cell pool to the proliferative compartment is quenched. Ultimately, after this overshoot, the oscillation is dampened by loss of mature cells, and homeostasis is restored.

ACKNOWLEDGMENT

We thank Patsy Saylor and Burt DeMill for their excellent technical assistance and Denise Huffines and Esty Daly for their secretarial support.

Proplatelets and Stress Platelets

By M. Tong, P. Seth, and D.G. Fenington

The process of platelet formation by the fragmentation of megakaryocyte pseudopodia, termed proplatelets, demonstrable in the marrow sinusoids is poorly understood. "Stress" platelets produced under conditions of stimulated platelet production differ from normal circulating platelets with respect to volume and a number of functional characteristics. To clarify the relationship of stress platelets to proplatelets, rats were injected with heterologous platelet antiserum. Nondiscoid platelet forms, some characteristically beaded in appearance, strongly resembling bone

marrow proplatelets, can be recovered in the circulation of normal rats. During the early period of recovery from acute thrombocytopenia, there was a substantial increase in the proportion of these elongated platelets in the citrated platelet rich plasma. Exposure to EDTA rendered them spherical. Circulating proplatelets may contribute significantly to the prompt increase in platelet volume during recovery from acute thrombocytopenia at a time prior to significant increase in megakaryocyte size and ploidy.

© 1987 by Grune & Stratton, Inc.

PLATELETS PRODUCED during recovery from acute thrombocytopenia show a striking increase in mean volume^{1,2} which under steady state conditions of increased production does not depart from a log normal size distribution.³ Odell and colleagues⁴ showed the appearance of large or "giant" platelets as early as 12 hours after the induction of thrombocytopenia well before any increase in the rate of platelet production could be expected. Although they are undoubtedly young platelets freshly produced by megakaryocytes in response to the acute stress of thrombocytopenia, caution must be exercised in equating them to normal young platelets. Hence, we adopted the term "stress platelets" to describe those platelets circulating during this period of accelerated platelet production.

A characteristic sequence of events in the bone marrow megakaryocytes following the administration of anti-platelet serum (APS) has been documented by a number of investigators. The first recognizable change within 2 to 6 hours in rodent bone marrow is the increase in the number of small acetylcholinesterase-positive diploid cells.^{5,6} This is followed in 18 hours of thrombocytopenia by an increase in the endomitotic index of the megakaryoblasts and subsequently an increase in the total number of immature megakaryocytes, most prominent at 40 hours.⁴ By 48 hours, there is a striking increase in the size of megakaryocytes in the marrow smear⁷; this is associated with an increase in the modal ploidy of the megakaryocytes from 16n to 32n that reaches a peak at 48 hours but returns to normal by 4 to 5 days.⁸ This increase in modal ploidy was also demonstrated by Levin and colleagues,⁹ who studied the effect of thrombocytopenia on ploidy distribution in megakaryocyte colonies obtained from soft agar culture. A significant number of 64n and even 128n cells is also present at 48 hours, whereas such cells are not readily detectable in the normal megakaryocyte colonies. Some investigators have suggested that this change in ploidy may determine platelet numbers¹⁰ and volume.¹¹⁻¹³ Although

this could be true in the "steady state," however, it cannot account for the early macrothrombocytosis observed by Odell and co-workers⁴ before any increase in endomitosis or in ploidy.

The presence of large intrasinusoidal cytoplasmic processes of megakaryocytes with relatively organelle-free constricted segments was demonstrated by Becker and de Bruyn¹⁴ and Radley and Scurfield¹⁵ using scanning electron microscopy, and these were termed proplatelets by Becker and de Bruyn. This led us to speculate that large circulating megakaryocyte fragments or proplatelets may contribute to the macrothrombocytosis that occurs in situations of altered platelet production; in many situations, their presence may have been obscured by the use of EDTA as an anticoagulant leading to the sphering of such proplatelet forms. This hypothesis has been tested in the rat.

MATERIALS AND METHODS

General. Adult Sprague-Dawley rats (250 to 400 g body weight) were used. Adult rabbits were immunized with a purified whole platelet preparation from rats by subcutaneous injections according to the schedule described by Vaitukaitis and co-workers¹⁶ to produce APS. The dosage (150–200 μ L/100 g per rat) of the APS (RBC- and WBC-absorbed and heat-inactivated) had been titrated in each batch to produce ~90% reduction of pretreatment platelet count at 24 hours after intravenous (IV) injection. Ether-anesthetized rats were injected with the appropriate single dose of APS through the jugular vein. Whole blood platelet counts were performed before and after APS treatment on EDTA-anticoagulated blood samples taken from the jugular vein. With 1% ammonium oxalate as diluent, a 1:20 dilution was made from the blood sample and platelets were enumerated under phase-contrast microscopy in a counting chamber. The anesthetized animals were killed by exsanguination at various intervals during a 168-hour period after APS treatment. Blood samples were harvested by inferior vena cava (IVC) or aortic puncture and were collected into either one of the following anticoagulants: ACDE₁—100 mL of acid-citrated dextrose containing 20 μ g/mL of prostaglandin E₁ (PGE₁), pH 6.7, 1 mL of freshly thawed ACDE₁ to 5 mL of blood; or EDTA dipotassium salt, 1.5 mg/1 mL of blood. Platelet-rich plasma (PRP) was prepared by centrifugation, 130 g for 15 minutes at 22°C in a swing-out rotor. At this speed, the average platelet recovery in the PRP was always >65%, with total RBC and WBC contamination <0.1%.

Platelet volume. Platelet counting and sizing were performed on PRP using a Coulter counter model ZF particle counter with a 50 $\times$ 60- μ mol/L aperture, coupled to a 2,000 channel multichannel analyzer. Latex spheres of 1.15- and 2.03- μ m diameter were used for calibration. No correction was introduced for the departure of

platelet shape from that of the reference sphere. Either ACDE₁ or EDTA was used as anticoagulant in the PRP. Final platelet concentration was adjusted to between 100 and $180 \times 10^9/L$ to minimize error due to simultaneous passage of multiple platelets through the aperture. Mean platelet volume (MPV) was calculated from the formula:

$$MPV = \sqrt{(\text{median}^3/\text{mode})},$$

according to Martin and colleagues.¹⁷ Volume measurement was routinely carried out 1 hour after blood collection—the time taken to prepare PRP plus 20 minutes standing at 22 °C, allowing platelets to recover in PRP from the trauma of collection.

Platelet morphology. The morphology of platelets was observed by phase-contrast microscopy. Differential counts on platelet morphology in PRP were performed at $\times 250$ magnification with the platelets drifting slowly between the coverslip and ordinary glass slide. The number of platelets counted in each sample ranged from 1,700 to 2,400 in normal rats to 200 to 900 in APS-treated rats.

Platelets were classified into the following forms: (a) discoid; (b) elongated—length greater than three times the width; (c) beaded forms—showing two or three well-formed cytoplasmic masses separated by constriction bands or slender cytoplasmic threads; and (d) strings—very long platelet processes, showing more than three beads and frequently folding upon themselves due to their excessive length.

For electron microscopy, PGE₁ at a dose of $0.5 \mu\text{g}$ was injected into the jugular vein of ether-anesthetized rats prior to blood harvesting. PRP was prepared from vena cava blood collected into syringes loaded with ACDE₁ and glutaraldehyde (final 0.1%) for prefixation. Platelet buttons were further fixed in 3% glutaraldehyde in 0.1 mol/L of sodium cacodylate buffer and postfixed in 1% osmium tetroxide, dehydrated in graded acetone, and then embedded in Spurr's resin. Sections were stained with uranyl acetate and lead citrate.

For scanning electron microscopy, nucleopore membrane filters (pore size $0.6\text{-}\mu\text{m}$ diameter) were used to filter the prefixed platelets from the PRP. The platelet-containing filter was then fixed in osmium and dehydrated in graded ethanol in the usual manner. It was then subjected to critical point drying by CO₂ and mounted on to stubs for gold coating. Statistical analysis was carried out by Student's *t* test unless otherwise specified.

RESULTS

Platelet counts. Figure 1 shows that at 24 hours after APS injection, the whole blood platelet count had dropped to $12.6\% \pm 5.5\%$ of the pretreatment value. Thereafter, the platelet count began to rise, being significantly above normal by day 4 and then returning to normal.

Mean platelet volume (MPV). Figure 2 shows that MPV measured in PRP anticoagulated with ACDE₁ was significantly increased for the first three days after APS treatment. On day 4 (96 hours) post-APS, when the rebound thrombocytosis was taking place, MPV was not significantly different from normal. The MPV correlated inversely with the degree of thrombocytopenia when the latter was expressed as a percentage of pretreatment platelet count ($P < .01$, $n = 25$, $r = .5560$, correlation coefficient and linear regression).

Morphology. Platelets in PRP (ACDE₁) were classified into different morphological forms by phase-contrast microscopy; their distribution is shown in Table 1. It is assumed that the nondiscoid platelets represent different morphological forms of proplatelets and their fragments. Pseudopod

Fig 1. Platelet counts at intervals after anti-platelet serum (APS) injection. Numbers indicate number of rats per point. Values were significantly different from control: * $P < .001$.

formation and other evidence of platelet activation was minimal. Prefixation of blood drawn into syringes containing 0.1% glutaraldehyde did not significantly affect the morphology of platelets. Approximately equal proportions of proplatelets were present in IVC and aortic blood of both normal or APS-treated rats ($0.3 > P > .2$). The proportion of proplatelets in the venous and the aortic circulation was significantly increased 2 to 3 times at 24 hours after APS treatment (venous $P < .01$; aortic $P < .001$). In general, proplatelets produced at this time appeared to be longer, were more frequently beaded, and showed a larger number of beads per fragment than that seen in normal animals (Fig 3). All platelets collected into EDTA were spherical and did not display the morphology of proplatelets (Fig 4). This is presumed to be due to the spherizing effect of EDTA, although fragmentation of some very long proplatelets into smaller spherical forms cannot be excluded. Citrated platelets are apparently protected from the spherizing effect of EDTA, since their subsequent exposure up to a final concentration of 10 mg/mL of EDTA for 30 minutes did not change their morphology perceptibly. These circulating elongated nondis-

ACDE₁, acid-citrated dextrose; IVC, inferior vena cava; APS, anti-platelet serum.

Percentage of platelets in platelet-rich plasma, mean ± SD.

At 24 hours after APS, the whole blood platelet counts were *9.5 ± 4.3% ($\bar{x}$ ± SD) and †8.0 ± 2.4% of the pretreatment platelet counts, respectively. There was no significant difference in the content of nondiscoid platelets between the above two blood circulations in either group of rats. The increase in beaded and string forms after APS treatment in either circulation did not reach statistical significance.

coid proplatelet forms are also readily demonstrable by transmission electron microscopy (Fig 5). Characteristic bundles of microtubules were seen, as described by Behnke¹⁸ in megakaryocyte pseudopodia and by Radley and Scurfield¹⁵ in proplatelets, running parallel to the long axis in the elongated proplatelets. Scanning electron microscopy also confirmed the presence of these elongated proplatelets among discoid platelets in the APS-treated rats (Fig 6).

DISCUSSION

It is now widely accepted that the megakaryocyte pseudopodia, first described by Wright¹⁹ in 1910 and subsequently recognized on phase contrast by Thiery and Bessis²⁰ and on electron microscopy by Behnke,¹⁸ actually penetrate the substance of endothelial cells to reach the marrow sinusoid^{14,15,21-23} and that platelets are not produced by direct

Fig 3. Phase-contrast micrographs of platelet-rich plasma anticoagulated with acid-citrated dextrose (ACDE₁) in (A) normal rats; and (B) in treated rats 24 hours after anti-platelet serum. In the latter, the numerous nondiscoid elongated forms and those showing constriction bands are collectively referred to as proplatelets. Examples of different platelet morphology are indicated: d, discoid platelet; e, elongated form; b, beaded form; s, string form.

Fig 4. Phase-contrast micrography of platelet-rich plasma anticoagulated with EDTA in (A) normal rats; and (B) in treated rats 24 hours after anti-platelet serum. All platelets are spherical, and proplatelet forms are conspicuously absent.

shedding from megakaryocyte cytoplasm extravascularly within the bone marrow. The thrombopoietic megakaryocytes described by Paulus²⁴ in collagenase-digested marrow suspension are highly irregular in shape with multiple cytoplasmic extensions. By scanning electron microscopy, these long projections of megakaryocytes can be demonstrated in the marrow sinusoids^{14,15} and were termed proplatelets by Becker and de Bruyn.¹⁴ The parasinusoidal position of megakaryocytes in the bone marrow²⁵ and their extensive internal demarcation membrane system, thought to act as a reservoir of surface membrane,²⁶ are likely to facilitate this process of

pseudopod or proplatelet production. The actual mechanism of intraendothelial penetration and segment detachment in the sinusoid is not known. Speculation is focused at the possibility of cytoplasmic gel-sol transformation²⁷ made possible by the fluid nature of the demarcation membrane system through fusion-fission reorganization and its capacity for both evagination and invagination.²⁸

As the proplatelet processes first enter the sinusoids, they appear as villi containing longitudinally aligned microtubules and microfilaments.¹⁵ Similar pseudopod formation by megakaryocytes can be demonstrated in short-term *in vitro*

Fig 5. Transmission electron micrographs of acid-citrated dextrose (ACDE₁) anticoagulated platelet preparations in (A) normal rats; and (B) in treated rats 24 hours after anti-platelet serum. In the latter, a very long proplatelet with constriction bands is shown with its bundles of microtubules running longitudinally (↑).

Fig 6. Scanning electron micrograph of platelets in (A) normal rats; and (B) in treated rats 24 hours after anti-platelet serum, showing the distinct contrast between discoid and elongated proplatelet forms ($\uparrow$). Other nondiscoid and tear drop forms (T) are also present (filter pore diameter 0.6 μ m).

cultures; by disassembling microtubules in vitro with vincristine or cold, the whole process of ribbon-like proplatelet formation can be reversed, indicating the importance of tubule structures in this process of proplatelet formation.²⁶ Recently, this process was recorded by time-lapse cinematography by Haller and Radley²⁹ on short-term culture of mouse megakaryocytes. The putative platelets in the chain of proplatelets exhibited some features common to circulating discoid platelets. These included flattening onto a glass surface and fine pseudopod formation comparable to that seen when platelets form. Rupture of the chains and release of platelets was not observed under in vitro conditions by these investigators, however, who postulated that individual platelets "bud off" from the proplatelets.

Using ACDE₁ as an anticoagulant, we described the presence of proplatelets in IVC and aortic blood of normal rats. These are not seen when EDTA is used as anticoagulant. Their features strongly resemble those of megakaryocytic proplatelet processes observed on scanning electron microscopy in marrow sinusoids. The circulating string forms represent proplatelet chains which would be expected to fragment further into shorter beaded forms. The smaller elongated forms may represent putative platelets that wait to be organized into discoid forms with the characteristic marginal microtubular bundles. During recovery from acute thrombocytopenia, the relative frequency of proplatelets and their nondiscoid fragments was increased threefold in the circulation; these included long segments with branches (Fig 7). Constrictions along the cytoplasmic processes are presumed to be the sites of future separation; hence, their distribution would dictate the platelet number and size to be produced. This hypothesis could be further tested by measurements of the distance between these constrictions in the

Fig 7. Phase-contrast micrograph of a branching proplatelet surrounded by a number of intact and fragmented RBCs together with various contaminant particles. What determines the number and location of the constrictions ($\downarrow$) in the proplatelet is not clear.

proplatelets of normal and acutely thrombocytopenic rats and comparison with the relative platelet volumes in these two situations. We propose that proplatelet chains break into fragments of lesser length at their narrowest, and presumably weakest, constriction sites rather than freeing individual platelets in a sequential manner from their distal ends. Such fragmentation may well occur within the microcirculation when proplatelets are caught astride bifurcating vessels. Subsequently, these circulating proplatelets must undergo internal reorganization into discoid platelets, presumably while "tumbling" in flowing blood or by some other mechanisms, because this change has not been observed in vitro.²⁹ Precisely how the lengthwise running microtubules of proplatelets rearrange themselves into the characteristic circumferential marginal microtubules of the discoid platelets remains to be determined.

Observations of circulating megakaryocytes³⁰ and pulmonary megakaryocytes³¹ both originating from the transmurular migration of whole megakaryocytes through the walls of the bone marrow sinusoid²¹ have been suggested as support for the notion of pulmonary platelet production.³²⁻³⁵ We failed to show any significant difference in proplatelet concentration between the venous and aortic circulation in both normal and APS-treated rats. The fact that bare nuclei of megakaryocytes are seen in bone marrow^{14,18} indicates that shedding of cytoplasm with production of proplatelets in marrow sinusoids must occur, as described by Becker and de Bruyn,¹⁴ and Scurfield and Radley.²² Our demonstration of free proplatelets in central venous circulation strongly reinforces this view. Twenty percent to 50% of mature megakaryocytes have been claimed to pass to the lung from the marrow.^{35,36} We assume that proplatelets are also released by these cells into the pulmonary venous circulation. The relative contribution of bone marrow and lung in platelet production has yet to be determined accurately.

This study demonstrated that beaded proplatelets representing fragments of megakaryocyte pseudopodia released

from marrow sinusoid can be recovered in the normal circulation. The proportion of these circulating proplatelets increased approximately threefold 24 hours after the induction of acute thrombocytopenia at a time prior to any significant increase in megakaryocyte size, ploidy, and number.^{7,8} During this recovery period, the proplatelets were visibly longer and more often beaded. These changes presumably resulted from accelerated proplatelet release from mature granular megakaryocytes in response to the thrombocytopenic stimulus. If proplatelet volume is four times greater than normal MPV, the increase in MPV observed at 24 hours could be entirely accounted for by the presence of >16% of proplatelets. The clear relationship between MPV and platelet count in the steady state observed by Levin and Bessman³⁷ and Giles³⁸ suggests, however, that fragmentation of proplatelets may give rise to discoid platelets of varying MPV depending on the circulating platelet count.

The morphology of these proplatelets is strikingly influenced by the anticoagulants used. Disassembly of their microtubules removes their elongated form even before release from megakaryocytes.²⁶ Like normal platelets, they are spheroid by EDTA (Fig 4). Macrothrombocytes appearing in idiopathic thrombocytopenic purpura (ITP) or other clinical conditions associated with altered platelet production such as myeloproliferative disorders may include a significant number of proplatelets spheroid by EDTA prior to preparation of blood smears. The megathrombocyte of the peripheral blood film³⁹ therefore may be either a spheroid "young" proplatelet or the "large" end of the log-normal distribution.

Antibodies to Granulocyte Precursors in Selective Myeloid Hypoplasia and Other Suspected Autoimmune Neutropenias: Use of HL-60 Cells as Targets

By Mark S. Currie, J. Brice Weinberg, Pradip K. Rustagi, and Gerald L. Logue

Patients with syndromes of autoantibody-mediated hemacytopenias may manifest signs of increased cell destruction and/or decreased cell production, depending on the maturity of the target cell and the effects of antibody binding. The purpose of this study was to use a cultured human cell line of hematopoietic origin for in vitro assays of antibody binding to overcome the relative inaccessibility of natural human marrow progenitor cells. This report describes the detection, using radioiodinated staphylococcal protein A (SPA), of antibodies binding to a human promyelocytic cell line (HL-60) in sera from three patients with chronic idiopathic granulocytic hypoplasia ("pure white cell aplasia," PWCA) and 22 patients with other syndromes of suspected immune neutropenia. Bone marrow from patients with increased IgG binding to HL-60 cells showed <15% granulocytic lineage cellularity in 11 of 17 cases. In vitro differentiation of HL-60 cells by retinoic acid resulted in increased IgG binding for sera that had shown

increased IgG binding to mature granulocytes but not undifferentiated HL-60 cells; in contrast, for sera with antibodies to untreated HL-60 cells and for normal serum, in vitro differentiation had little effect on IgG binding. Antibodies eluted from mature granulocytes were similar to the parent serum regarding the ratio of IgG binding to mature cells v HL-60 cells. No sera from 19 patients with febrile transfusion reactions showed increased IgG binding to HL-60 cells in the absence of increased IgG binding to mature granulocytes, although two sera had antibodies to both cell types. The use of HL-60 cells as targets may permit measurement of serum antibodies associated with granulocytic hypoplasia. In combination with assays to detect antibody binding to mature granulocytes, these techniques may discriminate among autoantibody specificities for antigens that are gained, conserved, or lost during myeloid maturation.

© 1987 by Grune & Stratton, Inc.

ANTIBODIES that bind to mature blood elements and their marrow progenitors have been detected in immune cytopenias affecting RBCs, platelets and neutrophils. Although assays for antibody binding to peripheral blood cells have been available for many years,¹ the detection of serum antibodies to early marrow precursors has depended primarily on use of in vitro clonogenic assays of marrow progenitor cells.² In the present study, we demonstrate the use of a human myeloid cell line (HL-60) to detect antibodies to granulocyte precursors in syndromes of immune neutropenia. The pathophysiologic significance of antibodies so detected is implied, in part, by clinical correlation of their presence with bone marrow myeloid hypoplasia.

MATERIALS AND METHODS

Cases. Patient 1 is a 69-year-old white man first noted to be neutropenic in early 1982. All hematologic values and serum chemistries were in the normal range except for the granulocyte count (300/ μ L). Assays for rheumatoid factor, antinuclear antibodies, and VDRL were negative. Bone marrow biopsies show a cellularity of 20% with erythroid predominance (M/E ratio of 1:4) and no mature granulocytes. Wright's stain of the marrow aspirate showed no granulocyte precursors beyond the late promyelocyte or early myelocyte stage. Average hematologic values from 1982 through 1985 are shown in Table 1. Physical exam showed no organomegaly and was remarkable only for ulatrophia. The patient has remained in excellent health except for one hospitalization, during which intravenous (IV) antibiotics were administered for an acute febrile episode without identified source of infection. He has also received penicillin VK (3 to 4 days every 2 to 6 months) for aphthous mouth ulcers or fever without identified source of infection. He takes no other medications and has no complaints other than occasional fatigue, and no other significant health problems have been identified.

Patient 2 is a 66-year-old black man who has been followed for neutropenia since 1982. Normal complete blood counts were documented in 1974 and 1976. In 1977, his hemoglobin, hematocrit, and platelet count were normal, but there were 1,200 granulocytes/ μ L and, in early 1982, 650 granulocytes and 100 monocytes/ μ L were recorded. Over the past 2 years, mean absolute granulocyte count has been 210/ μ L (Table 1). Radionuclide scan of the liver and

spleen was normal. Flow cytometric immunofluorescence analysis of peripheral blood lymphocytes to assess markers for B cells, helper, suppressor and total T cells, and natural killer cells showed no abnormalities. Serum protein electrophoresis showed a polyclonal increase in γ globulins to 20 mg/mL. At a 1:160 dilution, antinuclear antibodies with a speckled pattern were detected by indirect immunofluorescence using HEP-2 cell monolayer as substrate. Neither rheumatoid factors nor anti-DNA antibodies were detected. Bone marrow biopsies demonstrated a cellularity of 20% to 30% with erythroid predominance (M/E ratio of 1:10). Rare granulocytic cells beyond the myelocyte stage were present, and there were focal lymphoid aggregates with benign morphology. Bone marrow biopsies in 1982 and 1983 were both interpreted as "marked granulocytic hypoplasia." Complete blood counts on three first-degree and two

Table 1. Mean Hematologic Values for Three Patients With Selective Granulocytic Hypoplasia

Parameters	Total Leukocytes*	Neutrophils*	Monocytes*	Lymphocytes*	Platelets*	Hemoglobin†
Patient 1	2,600	230	560	1,600	219,000	14.4
Patient 2	1,200	210	140	780	218,000	10.6
Patient 3	2,800	900	600	1,200	182,000	12.7

Mean values were calculated from the results of 10 to 12 complete blood counts obtained on each patient at one- to six-month intervals between January 1982 and January 1986.

*Results are expressed as cells per microliter of whole blood.

†Hemoglobin is expressed as g/100 mL of whole blood.

second-degree relatives showed each to have a WBC count $>5,000/\mu\text{L}$. The patient was admitted to the Durham VA in March 1985 with fever, pain, and erythema of the right flank. Despite prompt institution of antibiotics appropriate to the *Staphylococcus aureus* subsequently cultured, the area progressed to abscess formation requiring surgical drainage. The patient has been on various β -blocker drugs since 1974 for idiopathic hypertrophic subaortic stenosis. He has also been treated at different times with digitoxin, quinidine, hydrochlorothiazide, and nitrates, but neither institution nor discontinuation of any of these drugs has been associated with a change in neutrophil counts.

Patient 3 is a 61-year-old black man followed since 1972 for mild depressive reactions and varicose leg veins. A normal WBC count was documented in 1957. In mid-1982, routine blood counts revealed neutropenia and he was referred for further evaluation. At that time, his WBC count was $2,500/\mu\text{L}$, of which 600 were neutrophilic granulocytes. His complete blood counts have remained remarkably stable, with mean hemoglobin of 12.7 g/dL, WBC count of $2,800/\mu\text{L}$, granulocytes $900/\mu\text{L}$, and monocytes $600/\mu\text{L}$ (Table 1). Bone marrow biopsy showed a cellularity of $\sim 30\%$ with erythroid predominance (M/E ratio of 1:4) with few mature granulocytes. He has been on no medications for several years and has suffered no unusual infections. None of the three patients has been transfused.

Buffers. The buffers used were: Veronal-buffered saline, pH 7.5 (VBS); VBS with 0.15 mmol/L of Ca^{2+} and 0.5 mmol/L of Mg^{2+} (VBSE); VBS with 0.1 mmol/L of EDTA (VBSE); VBS with 5% fetal bovine serum (FBS), (VBSF); Alsever's (acid-citrate-dextrose); Alsever's with 5% dextran (ACDD); phosphate-buffered isotonic saline with 2% paraformaldehyde (PFS); and VBS made 20% dimethylsulfoxide (VBSD).

Cells. Granulocytes were obtained from healthy volunteers with group O blood type. Venous blood was drawn into a heparinized syringe (10 U/mL of blood), diluted 9:1 with ACDD, and sedimented at 1 g for 1 hour at ambient temperature (RT). Granulocytes were separated from RBCs, lymphocytes, platelets, and plasma by centrifugation through a double layer of Ficoll-sodium diatrizoate mixtures with specific gravities of 1.077 and 1.120 as previously described.³ Granulocytes were collected from the 1.077/1.120 interface, washed twice in ACD, resuspended in ACD, and mixed with an equal volume of PFS. After incubation for 10 minutes at RT, the paraformaldehyde-fixed granulocytes (PFGs) were washed twice in VBS, resuspended in VBSD, and frozen at -70°C . Immediately before use, PFGs were thawed, washed in VBSE, and adjusted to a concentration of 20 to $30 \times 10^6/\text{mL}$. All washing was by centrifugation in 10 mL of buffer at 300 g for 10 minutes at RT. Thawed PFG preparations demonstrated $>95\%$ intact granulocyte morphology on Wright's-stained preparations. The HL-60 (human promyelocytic leukemia) cell line was from the American Tissue Culture collection. The cells used in differentiation experiments were from passage numbers 28 through 40. Cells were passed 2 to 3 times a week in RPMI 1640 with 10% FBS at 2 to 4×10^5 cells/mL. Cells used in initial IgG binding assays were harvested during log-phase growth,

washed in ACD, fixed, stored, and assayed like PFG. Freshly fixed HL-60 cells that had not been frozen were used for complement fixation assays. Leukemic myeloblasts and promyelocytes were obtained from the WBC-rich plasma of a patient with acute myelogenous leukemia, with a total WBC count $>100,000/\mu\text{L}$, of which 50% were promyelocytes and 50% were myeloblasts by Wright's stain morphology consistent with French-American-British (FAB) classification M2. These cells were also fixed, stored, and assayed in the same manner.

To study the effect of differentiation on IgG binding, cells were grown for 5 to 7 days concurrently under three conditions⁴ (a) in RPMI 1640 with 10% FBS alone (control), (b) in the same media with 1 $\mu\text{mol/L}$ of 13-*cis*-retinoic acid, or (c) with 12% (wt/vol) dimethylsulfoxide. Cells were harvested, counted, assayed for viability by trypan blue exclusion, and assayed for capacity to reduce nitroblue tetrazolium in the presence of 200 nmol/L of phorbol myristate acetate,⁴ or washed in ACD, fixed in paraformaldehyde, stored, and assayed in the same manner as PFGs and log-phase HL-60 cells. Granulocytes and log-phase HL-60 cells routinely demonstrated $>90\%$ viability prior to fixation. Viability was as low as 72% for cells cultured 7 days but was unaffected by the presence or absence of retinoic acid or dimethylsulfoxide (DMSO).

Sera. Sera were obtained, conforming to policies of Duke and Durham VA human subjects committees from normal donors, multiply transfused patients, and patients with suspected immune neutropenia (granulocytes $<2,000/\mu\text{L}$). Whole blood was clotted at room temperature, and the serum was removed and divided into 0.3-mL aliquots that were frozen at -70°C . For 1 year, ~ 200 sera were tested for evidence of antigranulocyte antibodies. All were tested for IgG binding to PFG as described below, and approximately one-fourth were also tested for IgG binding to HL-60 cells either because tests of IgG or IgM binding or C3 fixation to PFG were positive or because immune etiology was strongly suspected and/or clinical information (eg, chronicity, bone marrow findings) was sufficient to warrant further study. The patients' sera reported here are those that were "positive" (defined as more than two times normal IgG binding to PFG or HL-60 cells), and for which clinical information regarding drug use and associated disorders was known.

Eluates. PFG sensitized in undiluted serum were washed three times in VBS and resuspended in VBSE, and bound antibody was eluted in a fivefold volume of 1 mol/L of NaCl, 0.1 mol/L of citric acid pH 2.4 for 10 minutes at 4°C . After centrifugation at 2,000 g for 1 minute, the supernatant was removed and neutralized to pH 7.2 with 0.1 mol/L of NaOH. The eluate was then diluted to isotonicity (ratio of starting serum to final eluate volume was 1:20).⁵

Antibody testing. Radioiodinated SPA was used to quantitate granulocyte binding IgG.^{3,6,7} The target cells were incubated in a dilution of test serum (1:20 in VBSE unless otherwise specified) for 20 minutes at RT followed by 10 minutes at 37°C . After incubation, the cells were washed three times in VBSF and resuspended in 0.2 mL of VBSF, and 0.05-mL aliquots were incubated in triplicate with

5 ng of radioiodinated SPA (labeled by Bolton Hunter reagent to specific activity of 30 to 40 mCi/mg by Amersham) in 0.05 mL of VBS for 30 minutes at RT, layered over 0.1 mL of a 6:5 mixture of *n*-butyl and *bis*-hexyl phthalate oils. The remaining cell suspension was reserved for duplicate cell counts using a Coulter DN2. The cells were washed by centrifugation through the oil in a Beckman Microfuge B for 3 minutes, thus separating cell-bound from unbound SPA. The microfuge tubes were clamped beneath the aqueous oil interface, the tips were cut off, and the γ emissions were measured in a Beckman Gamma 4000. IgG bound is expressed for purposes of comparison as femtograms (fg) of SPA per cell. IgM binding was measured in the same way, except that radioiodinated monoclonal anti-human IgM (Boehringer-Mannheim) at 3 μ g/mL was substituted for SPA and 25 μ g of IgG (purified by ion-exchange chromatography from the serum of a patient with IgG multiple myeloma) was included to lower background binding of the radiolabeled antibody. The ability of sera to cause C3 fixation to PFG and HL-60 cells was measured in an assay similar to one we previously described.³ In this assay, the cells are incubated with test serum diluted 1:20 in VBSM for 15 minutes at RT, washed, and then resuspended in freshly thawed type AB serum at a final dilution of 1:10 in VBSM. The 37 °C incubation, washing, and radioligand binding steps are otherwise the same, except that radioiodinated monoclonal antihuman C3c (Bethesda Research Laboratories) at 6 μ g/mL is used for the final incubation. Assays of IgG and IgM binding to the washed cells that had been incubated with test serum plus the 2.5-fold excess of normal serum used as complement source gave very similar results to those for cells incubated in test serum alone. This suggests that increased antibody binding was due to specific antibody in test sera and that increased amounts of nonspecific antibody in the initial incubation did not affect results for this assay system. Other cell types including RBCs, lymphocytes, platelets, and paraformaldehyde-fixed blasts and promyelocytes (50% each) from a patient with acute myelogenous leukemia (FAB classification M2) were substituted in the above assays in some experiments. All cells except RBCs had been fixed in 1% paraformaldehyde for the assays reported.

RESULTS

Sera from the three described patients with selective myeloid hypoplasia bound significantly more IgG to HL-60 cells than did control sera ($P < 0.01$), whereas IgG binding to PFGs was not significantly different, ($P > .1$; Table 2). Thus, these neutropenic patients who did not have detectable serum antibodies to mature granulocytes, did have antibod-

ies to an immature myeloid cell associated with a marked reduction of bone marrow granulocyte precursors.

When sera from other patients with suspected immune neutropenia were tested, >20 had increased IgG binding to either HL-60 cells alone or to both HL-60 cells and mature granulocytes. IgG binding to PFG and HL-60 cells, quantitated as fg SPA/cell is plotted for normal and positive patient sera in Fig 1. A positive result was arbitrarily defined as greater than two times the mean value for normal serum. As depicted in Fig 1, patient groups could be divided into those whose sera showed increased IgG binding to PFG only (group I), both PFG and HL-60 cells (group II), or HL-60 cells only, as found for the three patients above (group III). Table 3 lists the bone marrow findings and the major associated drug or disease for the patients whose antibody testing results are plotted in Fig 1. Bone marrows from group I patients showed a normal or increased number of granulocytic cells, whereas those of group III patients had decreased myeloid cellularity. Findings were variable in group II patients, with some showing hyperplasia and some showing marked hypoplasia of the myeloid series. Consistency of findings associated with a given drug or disease could not be assessed in neutropenic conditions for which only one or two positive sera were identified. Four or more sera were identified, however, for patients with neutropenia associated with procainamide treatment, rheumatoid arthritis, and large granular lymphocytosis (LGL) (defined by the persistent

Table 2. IgG Binding to Granulocytes and HL-60 Cells for Normal and PWCA Sera

Sera	fg SPA/Cell	
	PFGs	HL-60
Normal (n = 9)	0.32 $\pm$ 0.10	0.24 $\pm$ 0.09
Patient 1	0.26 $\pm$ 0.08	0.75 $\pm$ 0.11
Patient 2	0.34 $\pm$ 0.14	0.69 $\pm$ 0.09
Patient 3	0.44 $\pm$ 0.06	0.93 $\pm$ 0.15

PWCA, pure white cell aplasia; SPA, staphylococcal protein A; PFGs, paraformaldehyde-fixed-granulocytes.

Patient sera were tested for IgG binding to each cell type on at least three occasions as described. Normal sera were included in each assay. The mean $\pm$ SD femtograms of SPA bound per cell is given for each patient and the group of nine normal sera. For HL-60 cells, patient results are significantly greater than normal ($P < .01$ by Student's *t* test).

Fig 1. IgG binding to mature granulocytes v HL-60 cells. Solid circles: IgG binding (as measured by mean staphylococcal protein A (SPA) bound per washed cell in two or more triplicate assays) to paraformaldehyde-fixed granulocytes (PFGs) and HL-60 for 33 individual sera tested at a 1:20 dilution. The mean and SD for nine assays of normal sera tested concurrently are depicted by the open square with vertical and horizontal brackets. Positive results for patient sera arbitrarily defined and grouped by values exceeding twice the normal mean for SPA binding to PFGs and/or HL-60 are indicated by the horizontal and vertical solid lines, respectively. Dashed lines drawn from the open square reflect a similar division of groups of sera according to the ratio of excess IgG binding to PFGs v HL-60. For clarity, data for 140 other patient sera that resulted in less than twice the mean SPA binding for normal subjects are not shown.

All patients had <2,000 granulocytes/ μ L when serum was obtained.

*The associated drugs or diseases were: C, cephalosporin; AMT, autologous marrow transplantation; LGL, large granular lymphocytosis; RA, rheumatoid arthritis; P, procainamide; HT, hyperthyroidism; HCL, hairy cell leukemia; HD, Hodgkin's disease; IM, infectious mononucleosis; AA, acute aplastic anemia; SS, "serum sickness"; LS, latent syphilis; CC, cryptogenic cirrhosis; and PWCA, chronic idiopathic myeloid hypoplasia or pure white cell aplasia; other abbreviations as in Table 2.

†Mean value of two or more assays is recorded. In a typical assay, the mean SE of triplicate results was 5%, with a maximum of 10%. Results for the same patient assayed on different days varied as much as 40%, but the SEM of three or more assays was usually <20%. For nine normal sera tested, the mean SPA binding was 0.32 ± 0.11 fg/PFG and 0.26 ± 0.10 fg/HL-60 cell.

‡Results for anti-IgM and anti C3c binding are recorded as positive (+) if ≥ 1.4 times the normal mean and as negative (-) if <1.4 times the normal mean.

§Myeloid cellularity was calculated from the percentage of overall hematopoietic cellularity and the myeloid/erythroid ratio in the official pathology reports if available. Myeloid cellularity is designated as decreased (↓) if <15%, as intermediate (I) if between 15% and 40%, and as increased (↑) if >40%. We confirmed results for 14 marrows available for review.

presence of >500/ μ L lymphoid cells with azurophilic granules on Wright's stain and/or HNK-1 monoclonal antibody binding on flow-cytometric immunofluorescence analysis of peripheral blood mononuclear cells). As shown in Table 3, observations based on these clinical associations were as follows. Sera from patients with procainamide-related agranulocytosis were in group II, demonstrating increased IgG binding and C3 fixation to both PFG and HL-60 cells. Patients with Felty's syndrome fell into both group I and group II, but all had PFG/HL-60 IgG binding ratios of ≥ 1

and their bone marrows did not show myeloid hypoplasia. Patients with LGL and neutropenia were noted in all three groups. Bone marrow biopsies were available from three patients with LGL (patient 6 in group I, patient 25 in group II, and patient 26 in group III). Marrow from patient 26 showed myeloid hypoplasia, whereas marrow from patient 6 was normocellular with a selective decrease in mature granulocytes. Marrow from patient 25 was 80% cellular with 65% replacement by abnormal lymphocytes (as compared with <10% lymphs for patients 6 and 26). The remaining patients

represent a variety of conditions in which immune neutropenia or other autoimmune phenomena have been described, as detailed in Table 3.

The different PFG/HL-60 IgG binding ratios that divide patients into groups demonstrating antibodies binding primarily to mature granulocytes (group I), immature myeloid cells (group III), or both (group II), might each be the result of single or combined antibody specificities for antigens that are variably expressed depending on the degree of myeloid maturation. To address the question of whether sera contained antigranulocyte antibodies to one or more than one antigen, several eluates were prepared from PFGs incubated in sera with different PFG/HL-60 IgG binding ratios. If a serum contained antibodies with multiple specificities differing in PFG/HL-60 binding ratio, one might expect the PFG eluate to show a higher PFG/HL-60 binding ratio than the original serum by virtue of a greater representation of predominantly PFG binding antibody in the PFG eluate. Alternatively, if a serum contained antibodies of a single specificity, so that the PFG/HL-60 binding ratio was determined by the ratio of antigen available on mature v immature cells, the PFG eluate and its parent serum should demonstrate the same PFG/HL-60 binding ratio. In Fig 2, the PFG/HL-60 binding ratio of serum is plotted against the ratio for the corresponding eluate assayed simultaneously. For the six sera tested, points fall on a line close to unit slope (0.84), consistent with a single specificity in each serum.

If the different PFG/HL-60 IgG binding ratios are due to different antibody specificities for antigens that are gained, conserved, or lost during neutrophil maturation, one might expect to see changes in antibody binding to HL-60 cells after in vitro differentiation. As illustrated in Fig 3, sera from group I patients showed an increase in IgG binding to HL-60 cells grown in the presence of retinoic acid or

Fig 2. Paraformaldehyde-fixed granulocyte (PFG)/HL-60 IgG binding ratios for serum v PFG eluates. For six sera (from patients 3, 11, 13, 17, 18, and 20) and the six eluates prepared from PFGs incubated in these sera, IgG binding to PFG and HL-60 cells was assayed simultaneously and the ratio of staphylococcal protein A (SPA) binding to each cell type was calculated. The ratios for each patient's serum and corresponding PFG eluate provide the coordinates for the six solid circles. Each falls close to a line with slope of 0.84, which intersects a line from the origin with unit slope at (1.3, 1.3). Unit slope is represented by the dashed line where points would be expected to fall if binding ratios were the same for eluate and serum. More selective PFG binding by eluates would cause points to fall to the right of the dashed line. The direction of deviation from unit slope and point of intersection may be explained by the effects of nonspecific IgG binding in whole serum, since normal sera give a mean PFG/HL-60 SPA binding ratio of 1.2.

Fig 3. Data from a representative experiment measuring the effect of differentiation on IgG binding to HL-60 cells. Cells were cultured for 7 days in the presence or absence of $1 \mu\text{mol/L}$ of 13-*cis*-retinoic acid (RA) and fixed. The percentage of increase in staphylococcal protein A (SPA) bound to retinoic acid-treated cells as compared with control HL-60 cells is plotted for normal serum and sera from patients in each of the previously defined groups. In this experiment, 22% of control HL-60 cells reduced nitroblue tetrazolium (NBT), whereas 61% of the RA-treated cells did. Similar results (not shown) were obtained in replicate experiments and also when cells were cultured in the presence of 1.2% dimethylsulfoxide (DMSO).

dimethylsulfoxide (DMSO). Essentially no change was seen for sera from patients in group II and group III. The HL-60 cell line may spontaneously lose the capacity to differentiate in response to these agents over time.⁸ Retinoic acid treatment of such HL-60 cells that have lost the capacity to differentiate (as assessed by morphology, nitroblue tetrazolium reduction, and anti-CR1 binding before and after 7 days of DMSO or retinoic acid treatment) in the course of prolonged continuous culture (>300 passages) failed to show any change in the amount of IgG bound by sera from group I patients. Thus, antibodies in sera from group I patients appear to bind to antigens acquired during differentiation.

The data for C3 fixation (Table 3) also suggest that mature granulocytes and HL-60 cells share antigens that are targets in immune neutropenia. Of 29 sera causing excess C3 fixation to one cell type, 22 (76%) caused excess C3 fixation to the other cell type as well, regardless of whether the ratio of IgG binding favored mature granulocytes (as with sera from neutropenic patients with rheumatoid arthritis) or HL-60 cells (as with sera from the myeloid hypoplasia patients). In contrast, $<2\%$ of sera tested have been found to cause excess C3 fixation to granulocytes in the absence of increased antibody binding to either PFG or HL-60 cells. Of the 29 sera reported here to cause at least 40% more than normal C3 fixation to PFG or HL-60 cells, we found only increased IgG binding and not IgM binding in 21, and increased binding of both immunoglobulin classes in 8. We have not identified sera that resulted in increased binding of anti-IgM to sensitized granulocytes at 37°C without also causing increased SPA binding. Thus, the potential importance of complement-fixing IgM antigranulocyte antibodies remains to be determined.

To demonstrate selective myeloid specificity of antibodies binding to HL-60 cells, sera from the three patients with

PWCA were tested for IgG antibody binding to RBCs, platelets, and lymphocytes from a normal group O donor and to the blasts and promyelocytes from a patient with acute myelogenous leukemia. Serum IgG binding to RBCs, lymphocytes, and platelets was no different for the three PWCA patients as compared with normal control subjects. As Fig 4 shows, however, the sera from these three patients did show increased binding to freshly isolated acute myelogenous leukemia cells as well as to the in vitro-passaged HL-60 cells.

In data not shown, sera from two groups of multiply transfused patients were tested for IgG binding to HL-60 cells. The first group of sera were from nine patients who had received RBCs or platelets from ten or more donors because of cytopenias related to chemotherapy or marrow disorders. None of these sera were positive as previously defined. The second group of sera were obtained 2 to 5 days following report of a febrile transfusion reaction in 30 patients. Two sera bound more than twice as much IgG to HL-60 cells as compared with normal serum. Both these sera also bound more than twice normal amounts of IgG to PFGs. Thus, allosensitization resulting in antibodies that bind to HL-60 cells but not mature granulocytes was not observed.

Fifty sera from healthy donors aged 64 to 89 years (median 81) were also tested, and mean ($\pm$ SD) for SPA binding of 0.34 ($\pm$ 0.14) fg/PFG and 0.23 ($\pm$ 0.08) fg/HL-60 were not different from younger controls (Table 2). Values greater than twice normal were found for only 1 of these 50 sera, and this one sample caused increased IgG binding to both PFG and HL-60 cells.

DISCUSSION

One expects to see compensatory hyperplasia of marrow precursors in processes that cause cytopenia by an effect on the postmitotic, terminally differentiating cells. An apparent reduction in the proliferating pool of committed precursors implies, however, that the corresponding cytopenia is due to effects on the more immature hematopoietic progenitors. Although hematologic malignancies, infections, inflammatory processes, and bone marrow infiltrations may preferentially reduce one cell line more than others, the isolated

Fig 4. Results for triplicate assays of IgG binding to freshly isolated and fixed acute myelogenous leukemia, French-American-British classification M2 cells as compared with the HL-60 cells are shown for normal serum (open circles) and three patients with pure white cell aplasia (PWCA) (solid circles), with SE brackets for each value in femtograms of staphylococcal protein A per cell. The dashed line indicates unit slope.

reduction in a single cell line should raise the suspicion of an autoimmune process.

Suspected immune cytopenias with precursor cell hypoplasia have been associated with both serum (IgG $\pm$ complement) and cell-mediated (T lymphocyte) processes in studies based on in vitro clonogenic assays.⁹⁻¹⁹ Also, clinical responses to plasmapheresis²⁰ and antilymphocyte globulin treatments²¹ have suggested roles for antibody and/or effector cells in mediation of these disorders, but the detailed pathophysiology remains a matter of inference and speculation. In this study, we found evidence of antibodies specific for immature myeloid cells in a number of patients with apparent granulocytic hypoplasia. Three cases demonstrated acquired chronic hypoplasia of the granulocytic series. Although patient 2 had a mild reduction in RBCs, hypergammaglobulinemia, and a low-titer antinuclear antibody, these patients otherwise had no generalized hematologic disorders or associated systemic diseases. Because the PWCA patients were untransfused males, allosensitization could not explain the increased antibody binding to the HL-60 or FAB-M2 leukemic cells, and it is not a likely explanation for the findings in other patients in group III. The term "pure white-cell aplasia" as it has been applied to idiopathic, disease-associated, or drug-induced hypoplasia of the granulocyte series,¹⁶⁻¹⁸ is a misnomer since nongranulocytic leukocytes may be unaffected, and the variably severe reduction in the proliferative pool of granulocyte precursors reflects degrees of hypoplasia rather than aplasia. The term seems appropriate, however, in its implication of the analogy to "pure red cell aplasia" as applied to immunologically mediated hypoplasia of the erythroid series.⁹

It is difficult to prove that antibodies that bind to cells are the cause of syndromes such as blood cell cytopenias, particularly granulocytopenia. Both granulocyte production and the distribution of cells between the marrow, the marginal and circulating blood pools, and the tissues are subject to many variables. These factors make studies of antibody effects on granulocyte survival and kinetics more difficult to perform and interpret than corresponding studies on RBCs and platelets.²² Effects occurring in the bone marrow are even less accessible to observation. For the granulocyte, which is $\sim$ 10 days in production as compared with perhaps 10 hours in the circulation, immune damage in the marrow may be of central importance regardless of the maturity of the target cell. Using whole protein A-bearing staphylococci to detect IgG binding to peripheral blood and bone marrow slide preparations, Harmon and co-workers demonstrated a relationship between severity of neutropenia and the immaturity of marrow cells to which autoantibody would bind.²³ This assay as applied by others to cases of PWCA has been negative, however,^{16,17} perhaps because of an insufficient number of antigen-bearing target cells. Nevertheless, Levitt and others have provided strong evidence for IgG antibody mediation of idiopathic and drug-associated PWCA by demonstrating inhibition of CFU-GM growth in in vitro clonogenic assays of human marrow.¹⁶⁻¹⁹ Various studies have likewise suggested the presence of antibodies to RBC and platelet precursors in certain syndromes.^{11,12}

Because HL-60 cells appear to express the appropriate antigens, these readily available cells can be used to detect

antibodies to immature granulocyte precursors in a simple and quantitative manner. These cells can also be used as a source for specific identification of antigens by immunoprecipitation and/or immunoblotting procedures. This model may also be useful in analyzing disorders involving other cell types (eg, pure RBC aplasia, immune thrombocytopenia, aplastic anemia, vasculitides) by using other available human cell lines. Classification of syndromes of autoantibody-mediated granulocytopenia according to antigen targets will facilitate the analysis of pathophysiology and clinical characteristics. Antibodies to peripheral blood granulocytes with differing *in vitro* characteristics have been reported in association with many drugs and diseases, including rheumatoid arthritis, procainamide-related and idiopathic lupus, LGL, Hodgkin's disease, and other conditions.²²⁻³² The classification of antigranulocyte antibodies based on the binding ratio to mature v immature myeloid cells is another step toward identification of antigen specificities, which may have significant prognostic and therapeutic implications.

Studies using other human cell lines and correlation with serum effects on *in vitro* clonogenic assays of marrow progenitors may be useful in determining whether antigens not present on HL-60 cells (eg, HLA-DR) may be involved in some cases of antibody mediated myeloid hypoplasia and to what extent antibody binding to cell-line targets predicts inhibition in assays using bone marrow cells. These studies, though, could not be expected to detect antibody-mediated marrow damage due to very low-titer (predominantly marrow cell-bound) antibodies, or antibodies to antigens that are

sparse or only transiently expressed on target cells. Moreover, the demonstration of antibody binding to granulocyte precursors and/or serum inhibition in marrow progenitor assays can only suggest a possible mechanism of marrow injury and may not be sufficient to direct therapy.

In this report, we describe three patients with chronic idiopathic myeloid hypoplasia and the use of HL-60 cells to detect antibodies to immature myeloid cells in these and other patients in whom we did not detect antibodies to mature granulocytes. We also report the binding of antigranulocyte antibodies to immature myeloid cells in a subset of patients with detectable antibody binding to mature granulocytes. In the patients studied, antibodies to immature granulocytes were associated with myeloid hypoplasia. The detection of such antibodies in elderly patients with "idiopathic" or "benign" neutropenia and in other disorders in which autoimmune phenomena occur is consistent with an antibody-mediated mechanism of neutropenia. Further studies based on the use of continuously cultured human cell lines are expected to contribute to a better understanding of the pathophysiology of autoimmune phenomena.

ACKNOWLEDGMENT

We are indebted to Dr Harvey J. Cohen and Dr Jeff Crawford for their help and support, the hematologists of the Duke Private Diagnostic Clinic for referral of sera, Dr Michael Borowitz for flow cytometric immunofluorescent analyses, and Dr Wendell Rosse and Dana Devine for manuscript review and advice. We thank Rachel Narula for her expert technical work and preparation of the manuscript.

Spectrin Is Associated With Membrane-Bound Actin Filaments in Platelets and Is Hydrolyzed by the Ca^{2+} -Dependent Protease During Platelet Activation

By Joan E.B. Fox, Clifford C. Reynolds, Jon S. Morrow, and David R. Phillips

We recently showed that platelets contain submembranous actin filaments that are linked to glycoprotein (GP) Ib on the plasma membrane. In the present study, experiments were performed to determine whether spectrin was associated with these filaments. The membrane-bound filaments were isolated from Triton X-100 (Sigma, St Louis) lysates of unstimulated platelets by differential centrifugation. Platelet spectrin was detected immunologically by using antibodies against human brain and RBC spectrin. Immunoblots showed that platelet spectrin consisted of two polypeptides (mol wt 240,000 and 235,000) that were similar in apparent mol wt to those of the α and β chains of brain spectrin but differed slightly from those of RBC spectrin (mol wt 240,000 and 220,000). Immunoprecipitation experiments identified platelet spectrin as two minor polypeptides migrating on sodium dodecyl sulfate (SDS)-polyacrylamide gels between actin-binding protein (mol wt 250,000) and the platelet polypeptide P235 (mol wt 235,000). Immunoblots of fractions isolated from Triton X-100-lysed platelets revealed that the α and β chains of

platelet spectrin were associated almost entirely with the actin filaments that were linked to the plasma membrane. Little spectrin was recovered in the Triton X-100-soluble fraction or with the actin filaments that were not membrane bound. During activation of platelets with thrombin or ionophore A23187, the α and β chains of spectrin were hydrolyzed, generating a major degradation product of mol wt 160,000 and a minor one of mol wt 170,000. These two hydrolytic products were also generated in Triton X-100 lysates incubated in the presence of Ca^{2+} but were not produced when lysates were treated with leupeptin, ethylene glycol bis(β -aminoethyl ether)- N,N,N',N' -tetraacetic acid (EGTA), or N -ethylmaleimide, known inhibitors of the Ca^{2+} -dependent protease. These experiments show that spectrin is a previously unidentified component of the membrane-bound actin filament network and that hydrolysis of spectrin by the Ca^{2+} -dependent protease may regulate the interactions of the filaments during platelet activation.

PLATELETS HAVE a characteristic discoid shape that is rapidly lost when physiological agonists activate the platelets. The factors responsible for maintaining the discoid shape or directing the activation-induced changes are not well understood. Microtubules have been thought to be critical in regulating platelet shape,^{1,2} but the finding that agonists induce a change in shape even when microtubules are stabilized with taxol³ suggests that additional factors are involved.

We recently showed that platelets contain a peripheral layer of actin filaments that is linked by actin-binding protein to glycoprotein (GP) Ib on the plasma membrane.^{4,5} This membrane-bound layer of actin filaments is distinct from the rest of the cytoskeleton and might function as a membrane skeleton, stabilizing the shape of the unstimulated platelet.⁴

The only other cell known to contain a membrane skeleton that regulates the shape of the cell is the RBC (for review, see refs 6 and 7). In this cell, the major component of the membrane skeleton is spectrin, which consists of elongated heterodimers comprising an α chain (mol wt 240,000) and a β chain (mol wt 220,000). The heterodimers are associated head to head, forming tetramers. The tail regions of the spectrin tetramers bind to short actin filaments, cross-linking these filaments into networks. Spectrin also links the filamentous network to the RBC plasma membrane through ankyrin, which connects spectrin to the membrane glycoprotein known as band 3. An additional linkage to the membrane may be provided by protein 4.1, which binds to spectrin and is also thought to be associated with the membrane glycoprotein glycophorin.⁸

Proteins immunologically similar to RBC spectrin,⁹⁻¹⁴ ankyrin,^{15,16} and protein 4.1¹⁷⁻²¹ have been described in many nonerythroid cells, including platelets.^{15,19,21} This raised the question of whether these proteins might be associated with the membrane-bound actin filaments in platelets. In the present report, we (a) identify platelet spectrin as two

polypeptides of mol wt 240,000 and 235,000, (b) show that spectrin is selectively associated with the membrane-bound actin filaments, and (c) demonstrate that spectrin is hydrolyzed by the Ca^{2+} -dependent protease during platelet activation, when the cell undergoes dramatic changes in shape.

MATERIALS AND METHODS

Preparation of platelet suspensions. Venous blood was drawn from healthy adult donors, and platelets were isolated from it by centrifugation as described previously.^{4,22} When the platelet pellet was removed from the tube after each centrifugation, care was taken not to include any RBCs that were sometimes found tightly packed below the platelets. The washed platelets were finally resuspended at about 1×10^9 platelets/mL in Tyrode's buffer containing 138 mmol/L of sodium chloride, 2.9 mmol/L of potassium chloride, 12 mmol/L of sodium bicarbonate, 0.36 mmol/L of sodium phosphate, 5.5 mmol/L of glucose, 1.8 mmol/L of calcium chloride, 0.4 mmol/L of magnesium chloride, and 10 ng of prostacyclin/mL, pH 7.4. When platelets were to be subsequently activated by platelet agonists, prostacyclin was omitted from the Tyrode's buffer. Microscopic examination showed that no contaminating RBCs were present.

To obtain platelets in which the surface glycoproteins were ^3H -labeled, washed platelets were labeled by the sodium meta-periodate/sodium [^3H]borohydride method, as described previously.⁴ Platelet counts were made with a Coulter counter.

Incubations. For studies of intact platelets, platelet suspensions were stirred with 0.1 National Institutes of Health (NIH) U of thrombin/mL (a generous gift from Dr John W. Fenton II of the New York Department of Health, Albany) or with 1.0 $\mu\text{mol/L}$ of ionophore A23187 (Calbiochem, San Diego) as described previously.²³

For studies of lysed platelets, lysates were prepared by adding to platelet suspensions an equal volume of buffer containing 2% Triton X-100 (Sigma, St Louis), 100 mmol/L of Tris-HCl, 100 mmol/L of benzamide, and 2 mmol/L of phenylmethylsulfonyl fluoride (PMSF) (Sigma), pH 7.4. When indicated, leupeptin (Vega Biotechnologies, Tucson, AZ), ethylene glycol bis(β -aminoethyl ether)- N,N,N',N' -tetraacetic acid (EGTA), or N -ethylmaleimide (Sigma) was included in the buffer to inhibit activity of the Ca^{2+} -dependent protease. Lysates were incubated at 25 °C, and incubations were terminated by the addition of sodium dodecyl sulfate (SDS)-containing buffer.

Isolation of subcellular fractions. Platelets (500- μL portions) were lysed by addition of an equal volume of ice-cold buffer containing 2% Triton X-100, 10 mmol/L of EGTA, and 100 mmol/L of Tris-HCl, pH 7.4. In some experiments, as indicated in the text, actin filament depolymerization was induced by omitting EGTA from the lysis buffer or by omitting EGTA and including DNase I (2 mg/mL, Boehringer-Mannheim, Indianapolis). When EGTA was omitted, leupeptin (2 mg/mL) was included to inhibit activity of the Ca^{2+} -dependent protease. When DNase I was included, 2 mmol/L of PMSF and 100 mmol/L of benzamide were added to the lysis buffer to inhibit any protease activity present in the DNase I. Lysates were centrifuged at 100,000 g at 4 °C for 3 hours to obtain the Triton X-100-insoluble actin filaments and the Triton X-100-soluble fraction. To separate the membrane-bound filaments from the rest of the actin filaments, lysates were first centrifuged at 15,600 g at 4 °C for 4 minutes. The bulk of the actin filaments sedimented at these g forces. The membrane-bound filaments remained in the supernatant, however, and were subsequently isolated by centrifugation at 100,000 g at 4 °C for 3 hours.

SDS-polyacrylamide gel electrophoresis (PAGE). For analysis on SDS-polyacrylamide gels, 3 vol of sample were solubilized by addition of 1 vol of a buffer containing 8% SDS (wt/vol), 20% 2-mercaptoethanol (vol/vol), 40% glycerol (vol/vol), 0.008% bromophenol blue (wt/vol), 250 mmol/L of Tris-HCl, 20 mmol/L of EGTA, and 4 mg of leupeptin/mL, pH 6.8. Insoluble fractions were solubilized in the same buffer diluted four times with distilled water. All samples were incubated at 60 °C for 5 minutes to facilitate solubilization. Protein was electrophoresed through slab gels according to the method of Laemmli,²⁴ using 3% acrylamide in the stacking gel and either 5% or 7.5% acrylamide in the resolving gel. For detection of total protein, gels were stained with Coomassie brilliant blue or by a silver staining method.²⁵ For detection of ^3H -labeled glycoproteins by fluorography, gels were treated with EN ^{3} HANCE (New England Nuclear, Boston), dried, and exposed to x-ray film as described previously.⁴ Spectrin was detected on immunoblots as described below.

Antibody production and characterization. RBC ghosts were isolated and washed as described.²⁶ Spectrin was extracted from ghosts at 37 °C in a low-ionic-strength buffer and was further purified by gel filtration on Sepharose 4B as described by Tyler and colleagues.²⁷ Purified spectrin was electrophoresed on SDS-polyacrylamide gels containing 5% acrylamide. The gel was stained briefly (~5 minutes) with Coomassie brilliant blue, and the two major bands of mol wt 240,000 and 220,000 (corresponding to the α

and β chains of spectrin) were cut out of the gel in a narrow strip. The gel strip was washed, homogenized, and injected into rabbits as described previously.²⁸ Antiserum was isolated by centrifugation of clotted blood for 20 minutes at 30,000 g. The immunoglobulin G (IgG) fraction was precipitated two times at 4 °C with 40% ammonium sulfate, dialyzed into a buffer containing 100 mmol/L of sodium chloride, 0.02% sodium azide, and 10 mmol/L of sodium phosphate, pH 7.4, and stored at 4 °C.

Antibodies against human brain spectrin were raised as described.²⁹ Monoclonal antibody against the β chain of RBC spectrin was kindly provided by Dr Stanley Schrier of Stanford University. Antibodies against actin-binding protein and glycocalicin (the water-soluble hydrolytic product of GP Ib) were raised as described previously.^{4,28}

Antibody specificities were characterized on immunoblots as described previously.^{28,30} The specificities of the affinity-purified actin-binding protein antibodies and the glycocalicin antibodies have been described.^{4,28} Antibody concentrations were determined by their absorbance at 280 nm using an $E_{1\text{cm}}^{1\%}$ value of 14.0.

Immunoprecipitation of proteins from platelet lysates. Platelet suspensions (1 to 2×10^9 platelets/mL) were lysed by the addition of an equal volume of ice-cold buffer containing 2% Triton X-100, 10 mmol/L of EGTA, 2 mg of leupeptin/mL, and 100 mmol/L of Tris-HCl, pH 7.4. In some experiments, DNase I (1 mg/mL) was included in the lysis buffer to depolymerize actin filaments and release filament-associated proteins into the Triton X-100-soluble fraction. When DNase I was present, PMSF (2 mmol/L) and benzamide (100 mmol/L) were included in the lysis buffer and the leupeptin concentration was increased to 4 mg/mL. Filamentous actin remaining in the Triton X-100 lysates was removed by centrifugation of the lysates at 100,000 g at 4 °C for 3 hours. Proteins were immunoprecipitated from 1-mL portions of the Triton X-100-soluble fraction as described previously.⁵ Immunoprecipitated protein was solubilized with 70 μL of an SDS-containing buffer and analyzed on SDS-polyacrylamide gels.

RESULTS

Characterization of spectrin antibodies. RBC ghosts and washed platelet suspensions were each solubilized in SDS-containing buffer and electrophoresed on SDS-polyacrylamide gels containing 7.5% acrylamide. The polypeptides were transferred electrophoretically to nitrocellulose paper, which was then incubated with antibodies against spectrin. Figure 1 shows that antibodies against both RBC spectrin and brain spectrin reacted with the α chain of mol wt 240,000 and the β chain of mol wt 220,000 of RBC spectrin (Fig 1A and B, lane 1). The antibodies also reacted with several minor polypeptides of lower mol wt present in the RBC ghosts, an observation made previously by others.⁹ Antibodies against RBC spectrin were raised in three different rabbits. Two of the antisera did not react with any platelet polypeptide on immunoblots. As shown in Fig 1, however, one antiserum reacted with a closely spaced doublet in platelets (Fig 1A, lane 2). The doublet had a mol wt of 240,000, as indicated by its comigration with the α chain of mol wt 240,000 of spectrin in RBC ghosts. A doublet of similar mol wt was also recognized in platelets by the antibodies against brain spectrin (Fig 1B, lane 2). There was no indication of a polypeptide in platelets that comigrated with the β chain of mol wt 220,000 of RBC spectrin. A monoclonal antibody against the β chain of RBC spectrin did not react with any platelet polypeptide (Fig 1C, lane 2).

Fig 1. Characterization of spectrin antibodies. RBC ghosts ($\sim 25 \mu\text{g}$ of protein) (lane 1 in each panel) and washed platelet suspensions ($\sim 75 \mu\text{g}$ of protein) (lane 2 in each panel) were each solubilized in sodium dodecyl sulfate (SDS)-buffer and electrophoresed on SDS-polyacrylamide gels containing 7.5% acrylamide. The polypeptides were transferred to nitrocellulose paper, which was incubated with antibodies against (A) RBC spectrin (final concentration, $210 \mu\text{g}/\text{mL}$), (B) brain spectrin (final concentration, $120 \mu\text{g}/\text{mL}$), and (C) a monoclonal antibody against the β chain of RBC spectrin (final concentrations, $110 \mu\text{g}/\text{mL}$ for RBC polypeptides and $220 \mu\text{g}/\text{mL}$ for platelet polypeptides). Antigen-antibody complexes were detected by autoradiography after incubation of the nitrocellulose paper with ^{125}I -labeled Protein A.

To resolve the α and β chains of platelet spectrin, platelet polypeptides were electrophoresed on SDS-polyacrylamide gels containing 5% acrylamide. Figure 2A shows that the α chain of platelet spectrin comigrated with the α chain of mol wt 240,000 of RBC spectrin, whereas the β chain migrated to a point between the α and β chains of RBC spectrin, with a mol wt of 235,000. These were the only two polypeptides that reacted specifically with the spectrin antibodies. Although a few additional minor bands were apparent (Fig 2A), these represented nonspecific binding of the antibody, as indicated by their presence in control blots as well (Fig 2B).

Immunoprecipitation of platelet spectrin. Antibodies against both RBC spectrin and brain spectrin caused immunoprecipitation of two polypeptides of spectrin from platelet lysates (Fig 3A, lanes 3 and 4). The two polypeptides were precipitated from platelet lysates even by batches of RBC spectrin antibodies that did not interact with platelet spectrin on immunoblots. The polypeptides were present in very small amounts and were barely detectable over the background of other proteins that were recovered nonspecifically in the immunoprecipitates. Their identification as platelet spectrin was indicated by their absence from immunoprecipitates obtained with normal rabbit IgG (Fig 3A, lane 2), however, and their identification was confirmed on immunoblots showing that the two immunoprecipitated proteins reacted with antibodies against brain spectrin (Fig 3B). The α chain of platelet spectrin comigrated with the α chain of mol wt 240,000 of RBC spectrin, whereas the β chain had a mol wt that was higher than that of both the β chain of RBC spectrin and the platelet polypeptide of mol wt 235,000 (P235) (Fig 3A, lanes 3 and 4 as compared with lanes 5 and 6).

Fig 2. Detection of RBC and platelet spectrin on immunoblots of 5% acrylamide gels. RBC ghosts ($\sim 0.5 \mu\text{g}$ of protein) (lanes 1 and 2 in each panel) and washed platelet suspensions ($\sim 60 \mu\text{g}$ of protein) (lanes 3 and 4 in each panel) were solubilized in sodium dodecyl sulfate (SDS)-containing buffer. Solubilized proteins were electrophoresed on SDS-polyacrylamide gels containing 5% acrylamide, transferred to nitrocellulose paper, and incubated with antibodies against (A) brain spectrin (final concentration, $120 \mu\text{g}/\text{mL}$) or (B) an equal concentration of normal rabbit serum. Antigen-antibody complexes were detected by autoradiography after incubation of the nitrocellulose paper with ^{125}I -labeled Protein A.

To identify which of the polypeptides in whole platelets represented spectrin, platelets were solubilized in SDS-buffer and then electrophoresed through SDS-polyacrylamide gels containing 5% acrylamide. Most one-dimensional gel systems resolve the two major high-mol-wt proteins actin-binding protein (mol wt 250,000) and P235 (mol wt 235,000), but not additional polypeptides in this mol-wt region. By using 5% acrylamide and running the gels until the dye front was well off the bottom of the gel, we were able to resolve two additional polypeptides that were visible on Coomassie brilliant blue-stained gels at points between actin-binding protein and P235 (Fig 3, lane 1). These polypeptides migrated to the same position on the gels as the two polypeptides precipitated by the spectrin antibodies. They were not present in platelet lysates from which spectrin had been immunoprecipitated (data not shown). We conclude that these two additional polypeptides represent platelet spectrin. The two polypeptides of platelet spectrin were present in approximately equal amounts and represented very minor components as compared with actin-binding protein and P235.

Association of spectrin with actin filaments in platelets. To determine whether spectrin was associated with actin filaments, platelets were lysed with Triton X-100 and

Fig 3. Immunoprecipitation of platelet spectrin. Platelets were solubilized directly into sodium dodecyl sulfate (SDS)-containing buffer (lane 1) or were lysed with an equal volume of a buffer containing 2% Triton X-100, 10 mmol/L of EGTA, 100 mmol/L of Tris-HCl, 4 mg of leupeptin/mL, 2 mmol/L of phenylmethylsulfonyl fluoride (PMSF), and 100 mmol/L of benzamide, pH 7.4. The Triton X-100-soluble fraction was obtained by centrifugation of the lysate at 100,000 g for 3 hours at 4 °C. The precipitate resulting from immunoprecipitation of 650 μ L of the Triton X-100-soluble fraction with 180 μ g of normal rabbit IgG/mL (lane 2), 180 μ g of RBC spectrin antibodies/mL (lane 3), or 150 μ g of brain spectrin antibodies/mL (lanes 4 and 8) was solubilized in SDS-containing buffer. Solubilized proteins were electrophoresed on SDS-polyacrylamide gels containing 5% acrylamide. Lanes 5 and 7 contain purified RBC spectrin, and lane 6 contains platelet P235 purified as described previously.²⁸ Lane 9 contains the supernatant remaining after precipitation of platelet lysate with brain spectrin antibodies. In panel A, proteins were detected with Coomassie brilliant blue stain. In panel B, spectrin was detected on Western blots using antibodies against brain spectrin as described in the legend to Fig 1. ABP, actin-binding protein; P235, platelet polypeptide of mol wt 235,000 that appears to be similar to talin.³¹

the actin filaments were sedimented at g forces known to sediment all of the filamentous actin (100,000 g for 3 hours). Analysis of the Triton X-100-insoluble and -soluble fractions showed that spectrin was primarily recovered along with the Triton X-100-insoluble actin filaments (Fig 4A, lane 2 compared with lane 3). Because several other platelet proteins in addition to actin filaments are inherently insoluble in Triton X-100,⁴ the effect of depolymerization of the actin filaments on the Triton X-100 insolubility of spectrin was examined. Two depolymerizing agents were used: Ca^{2+} and DNase I. The addition of Ca^{2+} causes depolymerization of most of the actin filaments in platelet lysates, but not of the small pool of filaments that is membrane bound.⁴ Figure 4B shows that Ca^{2+} had little effect on the recovery of

Fig 4. Recovery of spectrin with Triton X-100-insoluble actin filaments. (A) Platelets were solubilized directly into sodium dodecyl sulfate (SDS)-containing buffer (lane 1) or were lysed by addition of an equal volume of a buffer containing 2% Triton X-100, 10 mmol/L of EGTA, and 100 mmol/L of Tris-HCl, pH 7.4. Lysates were centrifuged at 100,000 g at 4 °C for 3 hours. Total platelets (30 μ L) or fractions originating from 30 μ L of platelets were analyzed on SDS-polyacrylamide gels containing 5% acrylamide (Triton X-100-insoluble [lane 2] and -soluble [lane 3]). Spectrin was detected on immunoblots using antibodies against brain spectrin as described in the legend to Fig 1. (B) Platelet suspensions were lysed by addition of an equal volume of a buffer containing 2% Triton X-100, 10 mmol/L of EGTA, and 10 mmol/L of Tris-HCl, pH 7.4 (lanes 1), the same buffer lacking a Ca^{2+} chelator but containing leupeptin 2 mg/mL to inhibit activity of the Ca^{2+} -dependent protease (lanes 2), and the same buffer lacking a Ca^{2+} chelator but containing leupeptin 2 mg/mL and DNase I (2 mg/mL), 2 mmol/L of phenylmethylsulfonyl fluoride (PMSF), and 100 mmol/L of benzamide (lanes 3). Triton X-100-insoluble and -soluble fractions were isolated and analyzed for the presence of spectrin as described for panel A.

spectrin in the Triton X-100-insoluble fraction (lane 2 compared with lane 1). In contrast to Ca^{2+} , DNase I depolymerizes both cytoplasmic filaments and membrane-bound filaments.⁴ When DNase I was present at concentrations shown previously to depolymerize ~40% of the total actin filament content and release ~20% of GP Ib from the Triton X-100-insoluble fraction,⁴ the recovery of spectrin in the Triton X-100-insoluble fraction was also reduced (Fig 4B, lane 3 compared with lane 1). The differential effect of Ca^{2+} and DNase I on the recovery of spectrin in the Triton X-100-insoluble fraction suggests that spectrin is selectively associated with the membrane-bound actin filaments in platelets.

An additional characteristic of the membrane-bound filaments is that they can be separated from other platelet actin filaments by differential centrifugation of platelet lysates.⁴ Figure 5A (lane 2) shows that many of the actin filaments in platelets can be sedimented from Triton X-100 lysates by low-speed centrifugation. Little GP Ib is associated with these filaments (Fig 5B, lane 2). The membrane-bound actin filaments require higher speed centrifugation to be sedi-

Fig 5. Recovery of spectrin with the membrane-bound actin filaments. Platelets, surface labeled by the sodium metaperiodate/sodium [^3H]borohydride method, were suspended in Tyrode's buffer and solubilized directly into sodium dodecyl sulfate (SDS)-containing buffer (lane 1 in each panel) or lysed by addition of an equal volume of a buffer containing 2% Triton X-100, 10 mmol/L of EGTA, and 100 mmol/L of Tris-HCl, pH 7.4. Lysates were centrifuged at 15,600 g at 4 °C for 4 minutes, and the Triton X-100 supernatant was centrifuged at 100,000 g for a further 3 hours. The sediments obtained at low speed (lane 2 in each panel) and high speed (lane 3 in each panel) and the supernatant obtained at high speed (lane 4 in each panel) were analyzed on SDS-polyacrylamide gels containing 7.5% acrylamide (A) or 5% acrylamide (B and C). Polypeptides were detected with Coomassie brilliant blue stain (A), ^3H -labeled glycoproteins were detected by fluorography (B), and spectrin was detected on immunoblots using antibodies against brain spectrin (C). The protein analyzed in each lane originated from 30 μL of whole platelets. ABP, actin-binding protein; GP Ib, glycoprotein Ib.

mented (100,000 g for 3 hours). At this g force, there is increased sedimentation of several platelet proteins, including actin filaments and actin-binding protein (Fig 5A, lane 3) and GP Ib (Fig 5B, lane 3). This property of the membrane-associated actin filaments was used to provide further evidence that spectrin was selectively associated with these filaments. Figure 5C shows that, like GP Ib, little spectrin was associated with the actin filaments that could be sedimented from Triton X-100 lysates at low g forces (lane 2). Spectrin, like GP Ib, was primarily associated with the actin filaments requiring high-speed centrifugation to be sedimented (Fig 5C, lane 3).

It has been shown that actin-binding protein links actin filaments and GP Ib on the plasma membranes of platelets.⁵ To test whether spectrin was a component of this actin-binding protein-GP Ib linkage, actin filaments in platelet lysates were depolymerized with DNase I. The lysates were centrifuged at 100,000 g for 3 hours, and the resulting supernatant, which was free of actin filaments and contained proteins released from filaments during depolymerization, was used in immunoprecipitation experiments. Figure 6 shows that the actin-binding protein-GP Ib complex was precipitated from the high-speed supernatant by actin-binding protein antibodies (Fig 6A and 6B, lane 1) and by GP Ib antibodies (Fig 6A and 6B, lane 2). Spectrin antibodies precipitated spectrin (Fig 6A, lane 4) but not actin-binding protein (Fig 6A, lane 4) or GP Ib (Fig 6B, lane 4), indicating that spectrin is not a component of the actin-binding protein-GP Ib complex.

Hydrolysis of spectrin during platelet activation. Figure 7 shows that activation of platelets with the divalent cation ionophore A23187 resulted in hydrolysis of spectrin. The major degradation product was a polypeptide of mol wt

160,000. A minor degradation product of mol wt 170,000 was also apparent. The same degradation products were generated when platelets aggregated in response to thrombin (Fig 8). The major degradation product was apparent within seconds of addition of 0.1 NIH U of thrombin per milliliter. The amount of hydrolysis increased with time after thrombin was added (Fig 8, lanes 1 through 10). Hydrolysis was dependent on aggregation of platelets; it was not detected if platelets were prevented from aggregating by failure to stir the suspensions (data not shown).

Hydrolysis of spectrin by the Ca^{2+} -dependent protease in platelet lysates. It has been shown that the Ca^{2+} -dependent protease within platelets is activated when platelets aggregate after stimulation by thrombin, collagen, or ionophore A23187.²³ To determine whether hydrolysis of spectrin within aggregated platelets resulted from activity of the Ca^{2+} -dependent protease, platelets were lysed with Triton X-100 under conditions in which the Ca^{2+} -dependent protease was active. The degradation products produced in lysates were compared with those produced in intact cells. Figure 9A shows that spectrin was rapidly hydrolyzed. The major degradation product had a mol wt of 160,000. Products with a mol wt of 210,000 and 170,000 were also generated. These three new polypeptides arose from activity of the Ca^{2+} -dependent protease, as indicated by the inhibition of their generation by leupeptin and EGTA (Fig 9A, lanes 11 and 12). *N*-Ethylmaleimide, another inhibitor of the Ca^{2+} -dependent protease,³² also inhibited hydrolysis of spectrin (Fig 9A, lane 13). This inhibition, however, even at a concentration of 5 mmol/L of *N*-ethylmaleimide, was not as complete as with the other two inhibitors. Silver staining of SDS-gels showed that actin-binding protein and P235, the two major substrates of the platelet Ca^{2+} -dependent protease

Fig 6. Demonstration that spectrin is not a component of the actin-binding protein-GP Ib complex. Platelet suspensions were lysed with an equal volume of a buffer containing 2% Triton X-100, 10 mmol/L of EGTA, 100 mmol/L of Tris-HCl, leupeptin 4 mg/mL, DNase I (1 mg/mL), 2 mmol/L of phenylmethylsulfonyl fluoride (PMSF), and 100 mmol/L of benzamide, pH 7.4. Triton X-100-insoluble actin filaments were removed from the lysates by centrifugation at 100,000 g at 4 °C for 3 hours. Precipitates obtained from immunoprecipitation of 1 mL of the Triton X-100-soluble fraction with 4.5 μ g of actin-binding protein antibodies/mL (lane 1 in each panel), 1.3 mg of glycolaldehyde antibodies/mL (lane 2 in each panel), 1.3 mg of normal rabbit IgG/mL (lane 3 in each panel), and 1.3 mg of RBC spectrin antibodies/mL (lane 4 in each panel) were each solubilized in sodium dodecyl sulfate (SDS)-containing buffer. Solubilized proteins were electrophoresed on gels containing 5% acrylamide. Immunoprecipitated actin-binding protein and spectrin were detected with Coomassie brilliant blue stain (A); GP Ib was detected on immunoblots using antibodies against GP Ib (B). ABP, actin-binding protein; GP Ib, glycoprotein Ib.

identified previously,²⁸ were hydrolyzed at a rate similar to that of spectrin.

DISCUSSION

Proteins immunologically and functionally similar to RBC spectrin have been described in many nonerythroid tissues.⁹⁻¹⁴ The best characterized of these proteins, that found in brain, is referred to as fodrin, caldesmon, or brain spectrin. Brain spectrin, like RBC spectrin, is a tetramer in which $\alpha\beta$ heterodimers associate head to head and the tail regions bind to actin filaments.^{9,33} Despite the similarities in structure and function, the brain and RBC proteins do differ, as indicated by their peptide maps^{9,10} and the often weak reactivity of RBC spectrin antibodies against brain spectrin.¹⁰ The α chains, despite their similar molecular weights (~240,000), show different peptide maps; the β chains differ in both peptide maps and mol wt (~235,000 for brain spectrin as compared with ~220,000 for RBC spectrin). In

Fig 7. Hydrolysis of spectrin during activation of platelets with ionophore A23187. Platelet suspensions were solubilized in sodium dodecyl sulfate (SDS)-containing buffer (lane 1) or were stirred for 60 seconds at 37 °C with 1 μ mol/L of ionophore A23187 before solubilization (lane 2). Solubilized proteins were electrophoresed on SDS-polyacrylamide gels containing 5% acrylamide, and spectrin was detected on immunoblots using antibodies against brain spectrin as described in the legend of Fig 1.

general, the spectrinlike proteins in mammalian nonerythroid cells appear to have mol wts similar to those of brain spectrin. It is becoming increasingly clear, however, that more than one isoform of nonerythroid spectrin can exist, even within the same tissue.^{34,35}

Early attempts, using antibodies against RBC spectrin, failed to detect spectrin in platelets.³⁶ More recent experiments detected a single polypeptide that comigrated on SDS-gels with the α chain of mol wt 240,000 of RBC spectrin.¹⁹ Because only one chain was detected in the latter study, it was not clear whether platelets contained the RBC form of spectrin or a form more closely related to brain spectrin. Because of the often low reactivity of RBC spectrin antibodies against spectrin in other tissues, we used brain spectrin antibodies to probe for spectrin in platelets. These antibodies detected two spectrin polypeptides both on SDS-gels of immunoprecipitated proteins and on immunoblots of total platelet proteins. The α chain of platelet spectrin comigrated with the α chain of mol wt 240,000 of RBC spectrin, whereas the β chain had a mol wt of 235,000. Platelets did not contain a polypeptide that comigrated with

Fig 8. Hydrolysis of spectrin during activation of platelets with thrombin. Platelet suspensions were solubilized in sodium dodecyl sulfate (SDS)-containing buffer (lane 1) or were stirred at 37 °C with thrombin 0.1 NIH U/mL for 5 seconds (lane 2), 10 seconds (lane 3), 15 seconds (lane 4), 20 seconds (lane 5), 30 seconds (lane 6), 45 seconds (lane 7), 60 seconds (lane 8), 5 minutes (lane 9), and 10 minutes (lane 10) before solubilization. Also shown are samples from another experiment in which unstimulated platelets were solubilized with Triton X-100 and lysates incubated in the presence of Ca^{2+} for 10 minutes (lane 11) or 0 minutes (lane 12) before solubilization. Solubilized proteins were electrophoresed on SDS-polyacrylamide gels containing 5% acrylamide, and spectrin was detected on immunoblots using antibodies against brain spectrin as described in the legend of Fig 1.

the mol wt 220,000 chain of RBC spectrin; neither did a monoclonal antibody against the β chain of RBC spectrin react with a polypeptide in platelets. We conclude, therefore, that platelets contain only one form of spectrin and that it is different from RBC spectrin. The mol wts of the α and β

chains of platelet spectrin are similar to those of brain spectrin.

In RBCs, spectrin is the primary component of the membrane skeleton, a structure beneath the plasma membrane that regulates the shape of the cell.^{6,7} The membrane skeleton

Fig 9. Hydrolysis of spectrin by the Ca^{2+} -dependent protease in platelet lysates. Platelet suspensions were lysed by addition of an equal volume of buffer containing 2% Triton X-100, 100 mmol/L of Tris-HCl, 2 mmol/L of phenylmethylsulfonyl fluoride (PMSF), and 100 mmol/L of benzamidinium, pH 7.4, and incubated at 25 °C. The incubation times for the lanes in both panels were as follows: 0 minutes (lane 1), 5 seconds (lane 2), 10 seconds (lane 3), 15 seconds (lane 4), 30 seconds (lane 5), 2 minutes (lane 6), 5 minutes (lane 7), 10 minutes (lane 8), 15 minutes (lane 9), and 30 minutes (lane 10). Incubations were also performed for 10 minutes in the presence of 5 mmol/L of EGTA (lane 11), leupeptin 1 mg/mL (lane 12), or 5 mmol/L of *N*-ethylmaleimide (lane 13). Incubations were terminated by addition of sodium dodecyl sulfate (SDS)-containing buffer, and polypeptides were separated by electrophoresis on SDS-polyacrylamide gels containing 5% acrylamide. Spectrin was detected on immunoblots using antibodies against brain spectrin (A); other polypeptides were detected by silver staining of the SDS-gels (B). ABP, actin-binding protein; P235, platelet polypeptide of mol wt 235,000 that appears to be similar to talin.³¹

is composed of short actin filaments that are cross-linked into networks by spectrin, which also links the networks to the plasma membrane. Immunofluorescence studies of several cell types,^{10,11,14} including platelets,¹⁹ have indicated that spectrin lies just under the plasma membrane in these cells too, raising the possibility that nonerythroid spectrin functions in the same way as RBC spectrin. We recently reported that a small pool of the filamentous actin in platelets is associated with glycoproteins on the plasma membrane.^{4,37} We suggested that the membrane-associated filaments may function like the membrane skeleton of RBCs in that they may play a role in regulating the shape of the platelet.⁴ Because the filaments that are attached to the membrane glycoproteins can be separated from other actin filaments within platelets,⁴ it was possible to test whether spectrin was associated with the membrane-bound filaments. The results reported here show that spectrin is indeed associated with the membrane-bound filaments in platelets.

A previous study⁵ has shown that one of the major components of the membrane-bound filamentous network in platelets is actin-binding protein. Like spectrin, it associates head to head, and the free tails of the polypeptide chains bind to actin filaments.³⁸ Like spectrin in RBCs, actin-binding protein in platelets connects the cross-linked filaments to glycoproteins on the plasma membrane.⁵ The present study shows that although spectrin is an additional component of the membrane-bound actin filament network in platelets, it is present in very small amounts as compared with actin-binding protein, which is one of the major platelet proteins. These observations suggest that the membrane-bound filamentous network in platelets differs from RBC membrane skeleton in that in platelets, actin-binding protein provides the major linkage between actin filaments and the plasma membrane, whereas in RBCs, spectrin is the major component of this linkage. If spectrin functions in platelets in the same way it does in RBCs, it would be expected to link actin filaments to a plasma membrane glycoprotein. Although spectrin does not appear to be involved in the linkage between actin-binding protein and GP Ib, it may provide an additional linkage between actin and an as-yet-unidentified component of the plasma membrane. Alternatively, spectrin in nonerythroid cells may function differently from its counterpart in RBCs. There is some evidence, for example, that spectrin may associate with microtubules.³⁹ The potential role of platelet spectrin in linking the membrane-associated filaments to the plasma membrane glycoproteins, microtubules, or other actin filaments awaits further study.

One of the initial responses of platelets to stimulation is their transformation from discs into irregular spheres.⁴⁰ Later, platelets undergo dramatic changes in shape as they spread on surfaces⁴¹ or extend long filopodia during the process of clot retraction.⁴² By analogy to the RBC, in which alterations in the membrane skeleton produce changes in cell shape,⁴³ the early changes in shape that platelets undergo in

response to activation could result from reversible modifications of components of the membrane-bound filamentous network. The later changes in the shape of the platelet membranes are so dramatic that the membrane-bound network would probably have to be disrupted for these changes to occur. Such a disruption has been shown to result from activation of the Ca^{2+} -dependent protease within platelets. This protease hydrolyzes actin-binding protein,²⁸ resulting in release of the actin filaments from their attachment to GP Ib on the plasma membranes.⁵ The results presented here show that platelet spectrin is also a substrate for the Ca^{2+} -dependent protease and is hydrolyzed during platelet activation with a time course similar to that reported for hydrolysis of actin-binding protein and P235.^{23,28} We reported that the Ca^{2+} -dependent protease is only activated in stimulated platelets if the platelets are allowed to aggregate.²³ A similar aggregation dependency for the hydrolysis of spectrin within platelets was detected in this study. In platelet lysates, hydrolysis of spectrin by the Ca^{2+} -dependent protease resulted in generation of three degradation products (mol wt 210,000, 170,000, and 160,000). In intact platelets, in which hydrolysis was more limited, the mol wt 160,000 product was the most readily detected. The mol wt of this major degradation product is similar to the mol wt 150,000 reported by Siman and co-workers for the product of hydrolysis of brain spectrin by purified Ca^{2+} -dependent protease.⁴⁴

Many of the proteins that are considered candidates for linkage proteins between actin filaments and plasma membranes in non-muscle cells (for example, actin-binding protein, vinculin, α -actinin, protein 4.1, and P235) are substrates for the Ca^{2+} -dependent protease.^{28,31,45-47} Furthermore, it was recently shown that the Ca^{2+} -dependent protease, previously thought to be a cytosolic enzyme,³² can bind to RBC membrane in an interaction that activates the enzyme.⁴⁶ These observations, together with the finding that activation of the Ca^{2+} -dependent protease during platelet activation results in hydrolysis of actin-binding protein and disruption of the interaction between actin filaments and GP Ib, emphasize the importance of the Ca^{2+} -dependent protease in regulating the interaction of actin filaments with plasma membranes. The finding that spectrin is an additional component of the membrane-bound filamentous network in platelets and that it is hydrolyzed by the Ca^{2+} -dependent protease during platelet activation suggests still another mechanism for regulation of the membrane-bound actin filaments during platelet activation.

Leukemic Blast Cell Colony Formation in Semisolid Culture With Erythropoietin: A Case Report of Acute Poorly Differentiated Erythroid Leukemia

By Masao Tomonaga, Itsuro Jinnai, Masuko Tagawa, Tatsuhiko Amenomori, Kenji Nishino, Eiichi Yao, Hiroaki Nonaka, Kazutaka Kuriyama, Yoshiharu Yoshida, Tatsuki Matsuo, Michito Ichimaru, and Tadashi Suematsu

The bone marrow of a patient with acute undifferentiated leukemia developed unique colonies after a 14-day culture in erythropoietin (EPO)-containing methylcellulose. The colonies consisted of 20 to 200 nonhemoglobinized large blast cells. Cytogenetic analysis of single colonies revealed hypotetraploid karyotypes with several marker chromosomes that were identical to those found in directly sampled bone marrow. The concurrently formed erythroid bursts showed only normal karyotypes. No leukemic colony formation was observed in other culture systems with either colony-stimulating activity (CSA) or phytohemagglutinin-stimulated leukocyte-conditioned medium (PHA-LCM). The leukemic colonies exhibited a complete EPO-dose dependency similar to that of the patient's normal BFU-E. Although cytochemical and immunologic marker

studies of the bone marrow cells failed to clarify the cell lineage of the leukemic cells with extraordinarily large cell size, ultrastructural study revealed erythroid differentiation such as siderosome formation in the cytoplasm and ferritin particles in the rhopheocytosis invaginations. These findings indicate that the patient had poorly differentiated erythroid leukemia and that some of the clonogenic cells might respond to EPO in vitro. Corresponding to this biological feature, the leukemic cells were markedly decreased in number in response to repeated RBC transfusions, and partial remission was obtained. These observations suggest that erythroid leukemia distinct from erythroleukemia (M6) with a myeloblastic component, can develop as a minor entity of human acute leukemia.

L EUKEMIC CELLS from patients with acute myeloid leukemia (AML) can form colonies composed of leukemic blasts in semisolid medium containing colony-stimulating factor (CSF)^{1,2} or phytohemagglutinin-stimulated leukocyte-conditioned medium (PHA-LCM).³⁻⁶ Izaguirre and colleagues also developed a culture method containing PHA-stimulated T cell-conditioned medium (TCM) and obtained leukemic colonies from patients with acute lymphocytic leukemia (ALL).⁷ Recently, Dicke and co-workers reported a double-agar layer method with PHA and CSF in the underlayer and obtained leukemic colonies from patients with either AML or ALL.⁸ The clonogenic cells in these leukemic colonies were designated leukemic colony-forming units (L-CFU).^{9,10} Among various biological features of L-CFU so far elucidated, especially in the PHA-LCM system, self-renewal function as measured by secondary plating efficiency (PE2) appears to be of special importance because it defines the stem cell nature of at least a part of these cells.^{11,12} In this article, we describe the first instance of leukemic blast cell-colony formation in erythropoietin (EPO)-containing methylcellulose culture from a patient with acute undifferentiated leukemia with ultrastructural evidence of erythroid differentiation and distinct chromosomal aberration.

MATERIALS AND METHODS

Case Report

The patient, a 50-year-old man, was admitted to a local hospital on September 10, 1983, because of a heel bone fracture. No abnormality was found in his peripheral blood, but pancytopenia developed rapidly during the next 2 months. He was transferred to our department on November 21, 1983. On admission, he was anemic and appeared acutely ill. No lymphadenopathy or splenomegaly was found. The liver was palpated 3 cm below the right costal margin. The hemoglobin (Hb) level was 5.8 g/dL. The WBC count was $3.6 \times 10^9/L$ with 52% mature neutrophils, 40% lymphocytes, 2% eosinophils, and 6% monocytes. The platelet count was $41 \times 10^9/L$. Initial bone marrow aspirate was highly cellular, with 31.6% abnormal blast cells, 1.0% myeloblasts, 5.9% promyelocytes, 6.8% myelocytes, 7.4% metamyelocytes, 32.8% mature neutrophils, 1.6% pronormoblasts, and 2.8% normoblasts. Megakaryocytes were decreased in number. The abnormal cells were extraordinarily large (30 to 40 μm in diameter), had a finely reticulated chromatin pattern, and moderate to strongly basophilic cytoplasm with some vacuoles but no granules (Fig 1). A few cells resembled pronormoblasts on May-Grunwald Giemsa (MG)-stained film. The patient was given 3 U of packed RBC for the next 3 days and recovered. After this transfusion, peripheral blood findings improved and were stable for ~40 days with Hb 8.3 g/dL and WBC $4.55 \times 10^9/L$; bone marrow showed a marked reduction of abnormal cell percentage to 3.4%, and erythroblastic elements were elevated to 65.6% (December 20, 1983). On January 6, 1984, however, leukemic cells in the bone marrow again increased to 30%. A low-dose cytosine arabinoside (ara-C) regimen (10 mg/day, continuous intravenous (IV) infusion for 16 days) was begun. A partial remission, with <5% abnormal cells, was obtained (February 8, 1984), but the leukemic cells began to increase again (February 20, 1984). The patient was further treated with the same regimen for 32 days. A second partial remission was obtained (April 10, 1984) but was transient, with a resultant increase of leukemic cells to 10% (April 24, 1984). A more intensive chemotherapy with ara-C and daunorubicin did not induce remission, and the leukemic cell proliferation became extensive, with rapidly increasing hepatosplenomegaly. The patient soon died of pneumonia and intestinal bleeding.

Fig 1. May-Grunwald Giemsa (MG) stain of the initial bone marrow (November 28, 1983) shows an increase (31.6%) of primitive blast cells with uniformly large cell sizes, a finely reticulated chromatin pattern, and several vacuoles. A few of them resemble normal pronormoblasts, exhibiting concentric nucleus and deeply basophilic cytoplasm with perinuclear halo (original magnification $\times 400$; current magnification $\times 264$). These abnormal blasts were negative for myeloperoxidase, specific and non-specific esterases, and hemoglobin stains. The bone marrow has well-preserved normal granulocytic elements, but those of the erythroid series are markedly reduced in number.

Cytological Analysis

Cytochemical stains used were myeloperoxidase (MPO),¹³ dual-esterase stain for naphthol-ASD chloroacetate esterase and α -naphthyl butyrate esterase,¹⁴ acid phosphatase,¹⁵ β -glucuronidase,¹⁶ periodic acid-Schiff (PAS),¹⁷ and Hb.¹⁸ Ultrastructural study of bone marrow cells was performed by routine double staining with uranyl acetate and lead citrate and cytochemical staining for MPO.¹⁹

For immunological marker analysis, several monoclonal antibodies such as J5 (common ALL antigen, CALLA, Coulter Immunology, Hialeah, FL); Leu 1 and HLA-DR (Becton Dickinson, Mountain View, CA), and OKM 1 (Ortho Pharmaceuticals, Raritan, NJ) were used. Terminal deoxynucleotidyl transferase (TdT) was detected by indirect immunofluorescence using anti-TdT antibody (Bethesda Research Labs, Gaithersburg, MD).

Colony Formation

CFU-E and BFU-E Assay.²⁰ Bone marrow buffy coat cells were collected after centrifugation at 1,200 rpm for 10 minutes. Cells (2×10^5) were plated in 1.0 mL of α -medium containing a final concentration of 0.88% methylcellulose, 30% fetal calf serum (FCS), 1% bovine serum albumin (BSA) and 1 U/mL of EPO (step III, Connaught, Canada) and cultured in a 35-mm Falcon plastic dish. For testing EPO-dose response by L-CFU, BFU-E, and CFU-E, EPO was added to final concentrations of 0, 0.1, 0.25, 0.5, and 1.0 U/mL, respectively. CFU-E and BFU-E were scored at day 7 and day 14, respectively.

CFU-GM Assay.²¹ Bone marrow light-density mononuclear cells (10^5) were cultured in a 35-mm Falcon plastic dish containing 1 mL of α -medium with 0.88% methylcellulose, 20% FCS, 10% giant cell tumor-conditioned medium (GTC-CM) (GIBCO, Grand Island, NY). Cell aggregates consisting of >20 cells were scored as colonies on day 8.

L-CFU assay.⁴ T cell-depleted bone marrow mononuclear cells (2×10^5) were plated in a 35-mm Falcon plastic dish containing 0.88% methylcellulose and 10% PHA-LCM. After 7-day incubation,

cell aggregates consisting of >20 cells were scored as colonies. This method allowed the detection of L-CFU colonies in 32 (82.5%) of 40 AML cases.

Cytogenetic Analysis

Bone marrow cells were processed directly for chromosomal preparation, and cytogenetic analysis was performed using standard methods and/or the G-banding method.²²

Chromosome analyses of individual colonies were performed by our own method described elsewhere.²³ In brief, individual colonies were aspirated and transferred into a droplet (10 μ L) of prewarmed 0.075 mol/L of KCl solution placed on a poly-L-Lysine-coated slide (Sigma Chemical, St Louis). After thorough mixing, the slide remained for 35 minutes at 37°C to allow the cells to attach. The slide was fixed, first with 30% fixative (3:1 methanol:acetic acid diluted with 0.075 mol/L of KCl), second with 20% ethanol diluted with 0.075 mol/L of KCl, and third with 100% fixative. The slide was then flame-dried and stained with Giemsa and/or Q-banded. This method yielded analyzable metaphases even from small colonies containing <40 cells. All laboratory examinations and in vitro assays were performed with informed consent from the patient.

RESULTS

Cytological Features of the Leukemic Cells

The undifferentiated, extraordinarily large leukemic cells were MPO⁻, both types of esterase⁻, acid phosphatase⁺ (86%), β -glucuronidase⁻, PAS⁻, and Hb⁻. They were also ultrastructurally MPO⁻. Immunological marker study disclosed CALLA⁻, Leu 1⁻, TdT⁻, OKM1⁻, and HLA-DR⁺ (12%). Transmission electron microscopic examination revealed distinct siderosome formation in the cytoplasm of $<5\%$ of the leukemic cells and fairly abundant rhopheocytotic invaginations and vesicles containing ferritin particles in half of the leukemic cells (Fig 2A, B, C).

Cytogenetic Findings in Bone Marrow Cells

Results of the serial cytogenetic studies are shown in Table 1. Abnormal hypotetraploid karyotypes were found on initial examination. Most of them had several identical marker chromosomes (Fig 2A). Repeated examinations revealed a considerable karyotypic instability (data not shown). Normal karyotypes were also present, but as a minor population. During the first partial remission, a clone with hypodiploid karyotypes was also observed. The relationship of the hypodiploid clone to the hypotetraploid clone could not be clearly explained. The hypotetraploid clone may represent the giant leukemic blast cells because they are known to have an excess amount of chromosomal materials.

Leukemic Blast Cell Colony Formation in EPO-Containing Culture

Erythroid colony assay of the bone marrow performed at the time of partial remission (January 6, 1984) disclosed bizarre colonies (Fig 3) consisting of 20 to 200 large non-hemoglobinized cells as well as well-hemoglobinized erythroid burst formation (Table 2). These two types of colonies reached maximum number on day 14 and did not form a single mixed colony. The cells from the bizarre colonies were uniformly large blast cells on MG-stained cytospin-smears

Fig 2. (A) Transmission electron microscopic features of a leukemic blast. The blast is large ($40\ \mu\text{m}$), has prominent nucleoli, fine chromatin structure without condensation, elongated endoplasmic reticulum, and occasional lysosomal granules and lipids (original magnification $\times 9,200$; current magnification $\times 5,796$). It possesses both siderosome ($\rightarrow$) and rhopheocytotic invagination ($\blacktriangleright$). (B) Higher magnification of the siderosome (original magnification $\times 76,000$; current magnification $\times 47,880$). (C) Higher magnification of the rhopheocytotic invagination with ferritin particles (original magnification $\times 76,000$; current magnification $\times 47,880$).

and resembled the leukemic cells in the bone marrow. They were negative for Hb, dual-esterase, and MPO stains. Cytogenetic analysis from individual day 14 colonies including normal-appearing erythroid bursts obtained from the relapsing bone marrow (February 20, 1984) was performed (Table 3). Karyotypes from the bizarre colonies revealed hypotetraploidy with several identical marker chromosomes, indicating that they belonged to a single abnormal clone (Fig 4B). Furthermore, these karyotypes carried marker chromosomes identical to those observed in the hypotetraploid karyotypes of the directly sampled bone marrow (Fig 4A). In contrast, karyotypes from erythroid bursts were all normal, showing 46, XY.

No leukemic colony formation was observed after cultur-

ing with GCT-CM or PHA-LCM. The data of serial colony assays are summarized in Table 2. The numbers of CFU-GM and erythroid bursts had recovered considerably at the time of partial remissions.

†Counted on day 7 of culture.

specimen obtained on April 24, 1984. The response curve of L-CFU was similar to those of CFU-E and BFU-E but appeared to be slightly higher at EPO concentration of 0.1 U/mL. A few leukemic colonies with <30 cells developed spontaneously without EPO.

DISCUSSION

The extraordinarily large leukemic blast cells of this patient lacked evidence of differentiation toward specific cell lineage on conventional cytochemical and cell surface marker analyses. Ultrastructural investigation demonstrated, however, at least in some of the leukemic cells, distinct siderosome formation in the cytoplasm and ferritin particles in the rhopheocytotic invaginations on the cell surface membrane. These findings provide evidence of erythroid differentiation^{24,25} proceeding in the leukemic cell population. Recently, Reiffers and co-workers reported two similar cases of acute undifferentiated leukemia.²⁶ Clinical and hematologic features common to these three cases are (a) relatively advanced age (>50 years), (b) poor response to conventional chemotherapy, (c) low WBC count with minimal or absent leukemic blasts in the peripheral blood, (d) extraordinarily large leukemic cells, (e) high ploidy and instability of karyotype, (f) ultrastructural evidence of erythroid differentiation and (g) lack of simultaneous proliferation of peroxidase-positive myeloid precursor cells. These characteristics suggest the possibility that this type of acute leukemia is a clinical entity distinct from erythroleukemia (M6) with a myeloblastic component,²⁷ and may be a poorly differentiated type of acute erythremia.²⁸⁻³¹

It is not yet clear whether the immunologic markers of erythroid differentiation such as glycophorin A and spectrin can be demonstrated on these poorly differentiated leukemic cells. Detection of such markers using monoclonal or heterologous antibodies may reveal an erythroid nature of undiffer-

entiated leukemia.³²⁻³⁴ These markers were also demonstrated, however, on AML blasts³⁵ and K562 cells with simultaneous expression of myeloid antigen.³⁶ Therefore, combined ultrastructural and immunological analyses of future cases of undifferentiated leukemia must be conducted to clarify the kind of markers that provide the earliest and consistent evidence of erythroid differentiation in leukemic cells.

The bizarre nonhemoglobinized colonies that developed concurrently with the patient's normal erythroid bursts in EPO-containing culture apparently derived from the leukemic clone, as evidenced by the presence in single colonies of a common karyotypic abnormality identical to that of the leukemic clone in the bone marrow. The L-CFUs from our patient did not develop colonies in other culture systems with GCT-CM or PHA-LCM, indicating that the L-CFUs responded to EPO itself in the culture medium. There remains a minor possibility of response to another activity, however, such as burst-promoting activity (BPA) contaminating the partially purified EPO material. We found no report of leukemic blast cell colony formation in BFU-E assay or leukemic colonies expressing erythroid markers in other culture systems. Clonal culture studies in acute erythroleukemia (M6) are also few.^{37,38} Suda and co-workers examined colony formation in the bone marrow cells from four patients with erythroleukemia, using a plasma clot system containing EPO and Minden's PHA-LCM system.³⁷ They observed defective erythroid colony formation in all cases. They did not note blast cell colony formation in EPO-containing system, although the PHA-LCM system yielded blast cell colonies that evidenced granulocytic differentiation. Thus, their findings in erythroleukemia are distinct from our present observation.

The L-CFUs from our patient showed an almost complete dependency when EPO was added to the culture. The

†All metaphases were photographed and karyotyped.

‡Aspiration of each colony was performed on day 14 of culture. L-CFU: leukemic colony-forming unit.

Fig 4. (A) Representative G-banded karyotype of the metaphases obtained from directly sampled bone marrow (November 28, 1983) shows hypotetraploidy and several marker chromosomes. Most of the metaphases carry marker chromosomes, indicating that they belong to a single abnormal clone. (B) Q-banded karyotype of the metaphase obtained from a leukemic colony shows hypotetraploidy and several marker chromosomes. Markers 2, 3, 4, 7, and 9 are common between the metaphases, and markers 2, 4, and 9 are identical to markers 2, 4, and 6, respectively, of the karyotype of the direct bone marrow sample, providing evidence that the blast cell colonies derive from the leukemic clone.

Fig 5. Erythropoietin (EPO) dose-response curves. The response curve of leukemic colony forming unit (●) is similar to those of normal BFU-Es (■) and CFU-Es (▲), but the L-CFUs show a slightly higher sensitivity to EPO at a low concentration of 0.1 U/mL. A few small leukemic colonies developed without EPO. The colony numbers at EPO 1.0 U/mL were regarded as 100%.

dose-response curve was similar to those of the patient's own normal BFU-Es and CFU-Es, but the L-CFUs showed a slightly higher sensitivity at the lowest dose of EPO. Theoretically, this hypersensitivity may explain the *in vivo* growth advantage of the leukemic clone over the normal erythroid progenitors. The reduction of the leukemic cell number in the bone marrow was rapid and marked after repeated transfusions, suggesting that a kind of feedback phenomenon occurred and induced a clinical partial remission without the use of chemotherapeutic agents. This observation indirectly supports the view that the leukemic cell proliferation *in vivo* was at least in part dependent on a given concentration of EPO. The feedback phenomenon in our patient mimics the marked erythroid depression inducible in patients with erythroleukemia by hypertransfusion.³⁹⁻⁴¹

Leukemic blast cell colony formation has been observed in semisolid culture with either PHA-LCM, PHA-TCM, PHA plus CSA, CSA alone, T type hairy cell-conditioned medium or human bladder carcinoma cell line-conditioned medium

(HTB9-CM).⁴² Nothing is known at present about the kind of activity that in the various conditioned media stimulates L-CFUs and supports the cell lineage-specific differentiation of L-CFUs. Hoang and co-workers recently separated leukemic blast growth factor (LBGF) from BPA and possibly from GM-CSF by Sephadex G100 fractionation of HTB9-CM.⁴² Our observation of EPO dependent leukemic colony formation suggests that factor(s) requirement of L-CFU for

in vitro growth is considerably different in different types of acute leukemia.

ACKNOWLEDGMENT

Sensitivity to 5-Azacytidine of Blast Progenitors in Acute Myeloblastic Leukemia

By Chen Wang and E.A. McCulloch

In a previous study, we showed that the blast stem cells of acute myeloblastic leukemia (AML) were more sensitive to cytosine arabinoside (ara-C) when growing in suspension culture than during colony formation in methylcellulose. We suggested that the difference might be explained by considering the cellular mechanisms responsible for growth in suspension and colony formation. In the former, the clonogenic cells increase in number (self-renewal); in the latter, most of the divisions are terminal. The increased sensitivity to ara-C in suspension might then be attributed to its ability to inhibit self-renewal to a greater degree than cell division generally. A test of this hypothesis would be to compare the survival curves in suspension and in methylcellulose using a drug that spared or stimulated self-

renewal. Such an agent is 5-azacytidine (5-aza) and has the additional advantage that its analogue, 6-azacytidine (6-aza) has no effect on self renewal. The data supported the hypothesis, since clonogenic AML blasts were much less sensitive to 5-aza in suspension than in methylcellulose. The effect of 6-aza, while qualitatively similar, was much less marked. Controls showed that the difference in survival curves could not be explained on a kinetic basis or by the secretion of growth factors by 5-aza-treated cells. We suggest that a comparison of the effects of drugs in suspension and in methylcellulose may be useful in preclinical screening of putative anti-AML compounds.

©1987 by Grune & Stratton, Inc.

SELF-RENEWAL, the process through which stem cells give rise to daughters with sustained proliferative potential, is essential for the maintenance of normal or malignant hemopoietic clones. The blast progenitors in acute myeloblastic leukemia (AML) have been shown to be capable of self-renewal.¹ These malignant stem cells form colonies in methylcellulose-containing cultures when stimulated by appropriate growth factors.² A minority of cells from blast colonies form new blast colonies on replating.¹ Furthermore, clonogenic blast cells increase exponentially in suspension culture.³ Both these events can be measured quantitatively, and each may be considered a manifestation of blast self-renewal.

We suggested that self-renewal may be an important target for therapeutic agents used in the treatment of AML.⁴ First, there is a consistent association between high self-renewal capacity as measured by replating pooled blast colonies, (secondary plating efficiency, or PE2) and poor response to treatment.^{5,6} Second, we showed that cytosine arabinoside (ara-C), a drug included in most effective anti-AML regimens, decreases self-renewal of blast progenitors cultured in its presence.^{4,7} Recently, we found that ara-C is a more potent inhibitor of blast growth in suspension than of blast colony formation in methylcellulose.⁸ Moreover, preliminary data from a small number of patients provided evidence that the sensitivities of blasts measured in suspension were associated with outcome of treatment with ara-C, whereas similar survival curves obtained with the methylcellulose assay showed no such correlation.⁸

We postulated that ara-C appeared to be more toxic to growth of cells in suspension than to colony formation in methylcellulose because self-renewal was the predominant cellular event in the former, whereas colony formation reflected principally postdeterministic divisions. A test of this hypothesis would be to measure survival curves under both conditions, using an agent that increased self-renewal. The drug 5-azacytidine (5-aza) is an obvious candidate; not only does exposure to it increase self-renewal, but a control compound also exists. The analogue 6-azacytidine (6-aza) is cytotoxic but, unlike 5-aza, does not affect self-renewal.⁹

This article reports the measurement of 5-aza survival curves for AML blast cells exposed to the drug either in

suspension or in methylcellulose. As predicted, growth in suspension was less sensitive to 5-aza than was colony formation in methylcellulose.

MATERIALS AND METHODS

Leukemic cells. Heparinized peripheral blood was obtained from 20 patients with AML (French-American-British, FAB, classification M1 through M5)¹⁰ at the time of diagnosis or at relapse. The diagnosis was based on morphological and clinical criteria regularly used in clinical trials of patients with AML at the Ontario Cancer Institute.^{11,12} Only patients with a high percentage of blast cells in the peripheral blood were included in the study.

Preparations of blast cells free of contaminating T lymphocytes were obtained as described previously, using two Ficoll-Hypaque density-gradient centrifugations ($P = 1.007$), the second following the formation of sheep-erythrocyte rosettes.¹³ The cells were either placed in culture at once or preserved in liquid nitrogen in the presence of 10% dimethylsulfoxide (DMSO) and 50% fetal calf serum (FCS). In some experiments, cells were tested after being maintained for up to 3 months in suspension culture.

Assay for clonogenic blast cells. The assay for clonogenic blast cells was as described previously with the exception that media conditioned by the bladder cancer cell line HTB9 (HTB9-CM) was used as a source of growth factor.^{13,14} Blast populations were cultured in 35-mm Lux dishes (Miles Laboratories, Naperville, IL) in a medium consisting of α -minimal essential medium (MEM), 20% FCS (growth medium) and 10% HTB9-CM with 0.8% methylcellulose. The cultures were incubated for 7 days in a humidified atmosphere in the presence of 5% CO₂ in air at 37 °C, after which

time colonies containing >20 cells were counted, using an inverted microscope.

Measurement of the PE2. The secondary plating efficiency (PE2) was measured using the pooled colony technique described previously.¹ The cells were harvested from primary colonies, pooled, washed and replated in microwells at a cell density of 10^4 per well with media of the same composition used for primary cultures. Colonies with >20 cells were counted after 7-day incubation. PE2 was expressed as colonies per 10^4 cells plated.

Suspension culture method. Blast cells were cultured in suspension as described previously.³ As in the clonogenic assay, HTB9-CM was used rather than phytohemagglutinin-leukocyte conditioned medium (PHA-LCM) as a source of growth factor.¹⁴ The cells were suspended in growth medium at a concentration of 10^6 /mL in the presence of 10% HTB9-CM. After varying times of incubation, the cells were harvested and counted. Usually the cell numbers recovered at this point in the control groups were greater than the 10^6 cells/mL used at the beginning of the culture; the suspensions were washed and replated in methylcellulose for blast colony formation, as described earlier. This procedure provided a measurement of the number of clonogenic cells per dish recovered at each point of time in suspension culture. The calculation consisted of multiplying the number of cells recovered per dish (as determined before washing) by the plating efficiency in methylcellulose. In some instances, cells recovered from suspension culture were washed, resuspended at 10^6 /mL, and recultured in suspension.

Exposure to drugs. 5-Aza was obtained from Sigma Chemical, St Louis, and 6-aza (P-L Biochemicals, Milwaukee). The drugs were dissolved in phosphate-buffered saline (0.02 mol/L Na_2HPO_4 ; 0.02 mol/L NaH_2PO_4 , pH 6.5; 0.42 mol/L NaCl) just before use.¹⁵ Ara-C was obtained from Upjohn, Don Mills, Canada. Adriamycin was obtained from Adria Laboratories of Canada, Mississauga, Ontario. Cells in either methylcellulose or suspension cultures were exposed to increasing concentration of drugs in growth medium modified to exclude ribonucleosides and deoxyribonucleosides and buffered with HEPES. The survival curves were calculated by comparing the number of colonies or the number of clonogenic cells recovered at each dose with controls, cultured in the absence of drug. Simple negative exponential survival curves were obtained for blasts exposed to each of the drugs, either in suspension or in methylcellulose. These curves can be described by a single slope parameter, the dose required to reduce survival to 10% of control (D_{10}). A diagrammatic representation of the procedure for obtaining survival curves in methylcellulose and in suspension is given in ref. 8.

Stability of 5-Aza. Stability of the structure of 5-aza was determined by measuring absorption at 241 nm, using a Unicam sp 1800 spectrophotometer, as described by Notari and De Young.¹⁵ We consider this procedure satisfactory, although it does not detect the intermediate decay products that are disclosed by high-pressure liquid chromatography, since our concern was only with 5-aza in buffer rather than in a complex mixture of compounds.¹⁶

RESULTS

Figure 1 contains typical survival curves for blast stem cells maintained for 2 weeks in suspension culture and then exposed for 7 days to 5-aza, adriamycin, or ara-C, either in suspension or in methylcellulose. It is evident from Fig 1 that the comparisons of the survival curves in suspension and methylcellulose differed for the three drugs. As in previous studies,⁸ the adriamycin survival curves in suspension and methylcellulose were indistinguishable; in contrast, ara-C appeared more toxic to cells in suspension than to the same population in methylcellulose. The reverse was found for

Fig 1. Survival curves for cells exposed to 5-azacytidine (5-aza) (A), adriamycin (B), or cytosine arabinoside (ara-C) (C) either in methylcellulose or in suspension. In the former instance, the drug was included in the cultures used for colony formation. In the latter instance, the drug was present during 7 days of suspension culture; the cells were then washed and tested for colony formation in methylcellulose. The number of clonogenic cells in each culture was calculated from the number of nucleated cells recovered from the 7-day cultures and plating efficiency (described in text). The cells used for this experiment were maintained in suspension culture for 2 weeks. Error bars show SD. Survival curves were drawn by linear regression. This procedure yielded two curves for the experiment with adriamycin, but SD of the points overlap and the two curves are not different.

5-aza; for this drug, the D_{10} value in suspension was much greater than the D_{10} in methylcellulose. Similar data were obtained when cells were exposed to the three drugs after 3 months in suspension culture. Table 1 contains the data from 20 experiments comparing 5-aza survival curves for blasts obtained either freshly or after cryopreservation, as well as the D_{10} values in suspension and methylcellulose. Table 1 also shows the French-American-British (FAB) classification, the blasts in the peripheral blood, and the PE2 values for each patient. It is evident that the D_{10} values in suspension were always greater than the D_{10} values in methylcellulose ($P < .00001$); furthermore, there was no correlation between the two D_{10} measurements ($r = -.217$). In agreement with previous findings,⁹ colonies in methylcellulose surviving exposure to 5-aza usually had increased values of PE2. In 4 of the 20 examples, however, decreases were seen. As in previous experiments,⁹ treatment with 5-aza did not stimulate secondary colony formation if it was absent in controls (two examples in Table 1).

Controls. A number of controls were required to establish the validity of the differences in D_{10} illustrated in Table 1. First, the construction of survival curves depends on a linear relationship between the number of cells placed in culture and the growth observed at the end of the assay. Linearity has been shown for methylcellulose cultures; for the suspension assay, a linear relationship exists between the number of nucleated cells used to initiate the cultures and the number of clonogenic cells recovered from each dish after 7 days.³ It was still possible, however, that treatment with 5-aza might change this relationship. Figure 2 shows the results of testing for linearity both in control suspension cultures and in cultures containing 5-aza; linearity was maintained under both conditions.

5-Aza, 5-azacytidine; FAB, French-American-British classification; D₁₀, dose required to reduce survival to 10% of control; PE₂, secondary plating efficiency; M.C., methylcellulose culture.

*PE₂ values are the mean of four replicate microwells with 1×10^4 cells from primary methylcellulose culture. The 5-aza group was at a concentration of 1.0 μmol/L.

Second, the outcome of suspension cultures is more dependent than colony formation on growth kinetics; in the latter, the number of cell divisions occurring during the assay period is reflected in colony size and does not enter into the analysis unless the number of cells in each colony is reduced below the counting criterion of 20 cells to a colony. For the suspension method, however, the number of doublings in 7 days contributes directly to the number of clonogenic cells recovered in each dish. Controls were necessary, therefore, to test the

Fig 2. The linear relationship between number of nucleated cells added to suspension cultures and recovery of clonogenic cells after 7 days. Linearity is maintained in the presence of 5-azacytidine (5-aza). Error bars show SD; lines were drawn by linear regression.

possibility that the apparent difference in the survival curves in suspension and methylcellulose could be explained by growth kinetics in suspension. Blast cells were grown in suspension in the presence or absence of 5-aza at a concentration of 10^{-6} mol/L, a concentration that is close to the D₁₀ value in methylcellulose (Table 1). Two examples are illustrated in Fig 3. As anticipated, there was a sharp drop in clonogenic cells in each dish in the presence of drugs as compared with control. Suppression persisted for ~3 days and then growth resumed, with kinetics similar to the controls.

To exclude an early effect of 5-aza similar to that which occurred with ara-C, a detailed survival curve was prepared for cells maintained for >1 year in suspension and then exposed to 5-aza for 8 hours; the cells were then washed twice and either placed in suspension or plated in methylcellulose. The cells cultured in suspension were plated in methylcellulose after 7 days to obtain a survival curve in the usual manner. Figure 4 depicts the survival curves from this experiment, using the same cells, exposed to 5-aza briefly and then either plated directly in methylcellulose or maintained for 7 days in suspension. With this design, the reduction in growth in suspension was much less than that which occurred in methylcellulose.

Complete survival curves were also prepared for blast populations cultured for 3 days with or without 5-aza and then plated in methylcellulose to measure survival. Blasts exposed to 5-aza for 7 days in suspension or in methylcellulose were included in the same experiments as positive controls. Results from one of two similar experiments are shown in Fig 5. As in the curves prepared from cells exposed

to drug for 8 hours (Fig 4) or 7 days, the clonogenic cells exposed in suspension culture for 3 days were more resistant than in methylcellulose.

We also assessed the survival of the 5-aza structure. The drug was incubated in buffer without cells, using spectrophotometric absorption at 241 nm,¹⁵ as described in the Materials and Methods section. The drug was unstable, approaching undetectable levels after 3 days, a time consistent with the period of suppression of growth in culture.

As a third control, the effects of 6-aza were compared with those of 5-aza; survival curves were measured in seven experiments, both in suspension and methylcellulose. In agreement with the previous data,⁹ 6-aza was less toxic than 5-aza, using the clonogenic assay ($P = .04$). In contrast, in suspension, 6-aza was a more effective inhibitor than 5-aza ($P = .04$), although the D_{10} values in suspension for 6-aza were greater than the D_{10} values in methylcellulose ($P = .004$). For this subset of the data on blasts exposed to 5-aza, as for the whole data set, the D_{10} values for survival curves measured in suspension were much greater than those obtained using the methylcellulose assay ($P = .007$). Furthermore, the difference between survival curves in methylcellulose and in suspension for 5-aza was significantly greater than the differences for 6-aza ($P = .011$). Representative survival curves illustrating these features are shown in Fig 6.

Growth factor production. 5-Aza-treated blasts might show increased self-renewal as compared with controls if

Fig 4. Survival curves for blast progenitors exposed to 5-azacytidine (5-aza) for 8 hours in suspension and then cultured for 7 days either in suspension or in methylcellulose. Cells used in this experiment had been maintained for >1 year in suspension culture. Error bars are SD.

they were induced by the drug to secrete growth factors. Previously, we tested for this possibility, using cells that produced small amounts of growth factor; no increase was found following exposure to 5-aza.⁹ We extended these observations to cells that required HTB9-CM for growth and another blast population, representative of a rarer phenotype, in which good growth occurred in the absence of added HTB9-CM. For the former, it was necessary to add HTB9-CM to the cultures; therefore, controls were needed for the carryover of growth factors when the supernatants were tested for their effects on blast growth. This required titrations of HTB9-CM that had been incubated for 7 days in the presence of growth medium but without cells. For the population capable of sustained growth, these further controls were not required since these cells could be maintained in culture in the presence or absence of 5-aza without added growth factors. The results are given in Fig 7. All activity that occurred in cultures of cells requiring growth factor could be attributed to carryover of HTB9-CM; furthermore, no increase in growth-promoting ability was observed when

Fig 6. Representative survival curves for blast progenitors exposed to 5-azacytidine (5-aza) or 6-azacytidine (6-aza) in suspension or in methylcellulose. Lines were drawn by linear regression.

Fig 7. Experiments designed to show whether blast populations secreted growth factors active on blast cells. The top hatched area is the 95% confidence interval for blast cells exposed to 10% HTB9-conditioned medium (HTB9-CM). The lower hatched area is the 95% confidence interval for blasts exposed to 2% HTB9-CM, the amount calculated as present in the media of blast cells 7 days after culture, in which the cultures were initiated with 10% HTB9-CM. Colony number stimulated by the addition of conditioned media is shown on the vertical axis. The percentage and source of conditioned media under test is shown along the horizontal axis. Triangles (left panel) show the number of colonies stimulated by 2% or 10% HTB9-CM incubated for 7 days in the absence of cells. The activity was stable under these conditions. In the center and right-hand panels, open symbols represent results of supernatants from blast cells cultured in the absence of 5-azacytidine (5-aza); solid symbols represent supernatants of cultures in the presence of the drug. The middle panel (square symbols) shows results using cells that required HTB9-CM for growth; 20% conditioned media from these cells were less effective than the control values for HTB9-CM incubated for 7 days. Addition of 10% HTB9-CM to the blast supernatant yielded an activity equivalent to 10% HTB9-CM alone. The right panel (circles) shows data from cultures of cells that grew well without the addition of HTB9-CM. Supernatants from these cultures, with or without 5-aza, failed to stimulate blast colony formation. However, addition of 10% HTB9-CM gave the anticipated activity. Thus, blast cells in suspension did not secrete growth factors, nor did they when inhibitors were present.

5-aza was added at the time of culture initiation. Cells that grew without added HTB9-CM did not secrete blast growth factors when cultured for 7 days either with or without 5-aza. Controls in which HTB9-CM was added to supernatants from blast cultures were effective stimulators, indicating that residual cytotoxic drug or other inhibitors were not demonstrated in the supernatants.

Repeated exposure to 5-aza. The effects of 5-aza on blast progenitor self-renewal made it reasonable to question whether one more exposure to the drug would prolong the time for which blast progenitors could be maintained in suspension. Figure 8 shows the results of an experiment in which control and 5-aza-treated blast progenitors were maintained in suspension culture for 56 days. As in previous experiments of this design, the cells were harvested at weekly intervals, counted, washed, and recultured at $10^6/\text{mL}$. The data are presented as a cumulative growth curve, calculated on the basis of the changes occurring in each weekly culture period. One experimental group was exposed to 5-aza (0.5×10^{-6} mol/L) during the first week only; a second group was treated a second time between days 21 and 28. As

Fig 8. Kinetics of blast cell growth in controls and cultures exposed once or twice to 5-azacytidine (5-aza) at a concentration of 0.5×10^{-6} mol/L.

anticipated from the 5-aza survival curves for blasts in suspension, the single drug exposure led to a slight decrease in clonogenic cells after 7 days. Thereafter, the treated group contained more progenitors than did the control for 49 days; both then declined rapidly. The second drug treatment led to an immediate cessation of growth; the cultures could be maintained through only one subsequent passage. In this and three similar experiments, exposure to 5-aza did not prolong time in culture. Furthermore, the cytotoxic effects of a second drug treatment were much greater than at the first exposure.

DISCUSSION

The work described in this paper was undertaken to test and extend our previous observation that blast cells were more sensitive to ara-C when exposed in suspension than in methylcellulose culture. We proposed that this difference might be explained by findings indicating that ara-C was a more effective inhibitor of blast cell renewal than of terminal divisions.⁸ Thus considered, increased sensitivity in suspension reflected the predominant role of renewal in this assay whereas the terminal divisions occurring in methylcellulose were less affected by the drug. This hypothesis led to the prediction that a cytotoxic agent that increased the probability of renewal in surviving stem cells would be less toxic in suspension than in methylcellulose. 5-Aza has been shown to increase PE2 and was chosen for the test. Figure 1 shows that three classes of comparisons may be found when survival curves are measured for the same cells in suspension and methylcellulose. For adriamycin, an agent that is equally toxic for renewal and terminal divisions, the survival curves in suspension and methylcellulose were indistinguishable. As noted previously,⁸ ara-C was more sensitive in suspension than in methylcellulose. As predicted by the hypothesis, the findings with 5-aza were the reverse of those with ara-C; that is, the 5-aza D_{10} was greater for blasts exposed in suspension than for the same populations cultured with the drug in methylcellulose.

The validity of survival curves obtained using either the clonogenic assay in methylcellulose or growth in suspension is dependent on the linear relationship between input cells and the manifestations of growth after 7 days; however, when results obtained with the two assays are compared, the cellular events leading to the endpoints for each must be

considered. Colony formation in methylcellulose requires that a progenitor divide often enough to have at least 20 progeny. The natures of the divisions, renewing or terminal, do not enter into the assessment; neither is there added weight for large colonies. A kinetic component of the methylcellulose assay might emerge if the times of incubation were prolonged; however, this is not practical experimentally, since colonies usually disintegrate later.¹ In contrast, the assessment of the suspension assay reflects the number of renewing divisions occurring in 7 days; consequently, the measurement is very kinetics-dependent. The significance is apparent from the kinetic data presented in Fig 5, in which it is evident that the number of clonogenic cells recovered 7 days after exposure to 5-aza depends on both the inhibitory effects of drug during the 3 days it remains active and the subsequent recovery. A comparable recovery in colony formation in methylcellulose is unlikely because, as noted earlier, the colonies disintegrate after 7 to 8 days in culture and the number of clonogenic cells that can be recovered from the dishes also decreases markedly.¹ These findings are compatible with the postulate that conditions in methylcellulose are less favorable for growth than are conditions in suspension.

We chose to retain the 7-day interval for both assays as the basis for comparisons between them, even though this allows time for recovery in the suspension assay. The advantage is that regrowth of malignant stem cells after chemotherapy, a clinically important function, is retained. Studies in which the cells were exposed briefly to 5-aza in suspension and then either cultured in suspension or methylcellulose for 7 days also showed, however, that the progenitors were more resistant in suspension than in methylcellulose. Other experiments, in which blasts were exposed in suspension for 3 days and then plated in methylcellulose gave comparable results. Thus, it is improbable that the findings with 5-aza can be explained by the kinetics of recovery of drug-exposed cells.

The mechanisms underlying the generation of different survival curves in suspension and methylcellulose remain to be determined. We excluded drug-induced secretion of growth factors following treatment of cultured cells with either ara-C⁹ or 5-aza (Fig 7). Selection in suspension of a sensitive or resistant population of blast progenitors might

provide an explanation of the data. The results presented in Fig 1 argue against this possibility; the experiments were performed on cells that had been maintained in exponential growth for either 2 weeks or 3 months. Nonetheless, the comparison of survival curves observed for cells was similar to that observed with fresh samples and did not change when the time in suspension was extended.

The comparison of the effects of 5-aza and 6-aza may contribute to the explanation of the observed phenomenon (Fig 6). DNA hypomethylation is a known effect of the former but not the latter.^{17,18} In the clonogenic assay, 5-aza is more toxic than 6-aza; the reverse occurs when the suspension method is used. Thus, DNA hypomethylation may contribute to either the inhibitory effects of 5-aza in suspension or recovery from them. It should be noted that D₁₀ 6-aza values are greater in suspension than in methylcellulose, however, although the difference between the two culture conditions is significantly less than for 5-aza.

Despite its effect of self-renewal, 5-aza treatment did not facilitate the establishment of continuous lines. Instead, toxicity of the drug appeared to be cumulative, since a second exposure, 2 weeks after the first, with two intervening subcultures, led to a much greater decrease in growth than anticipated on the basis of the survival curves or response to a single exposure. The mechanism underlying these observations is unknown. It is striking, however, that blast cells, so aggressive in patients, cannot regularly be maintained indefinitely in culture. It may be that further improvements in the culture techniques are required to achieve long-term growth.

Finally, the hypothesis that differences in survival curves measured in suspension as compared with methylcellulose may reflect specific drug effects on self-renewal leads to the prediction that a correlation may be found between D₁₀ values in suspension and clinical outcome. For ara-C, preliminary evidence is available in support of the prediction.⁸ Unfortunately, the blasts used for the 5-aza experiments were obtained from patients at initial presentation and at relapse. This heterogeneity in the patient population is sufficient to prevent valid statistical analysis. More survival curves on blasts from newly diagnosed patients are now being collected.

Purification and Partial Amino Acid Sequence of Human Platelet Membrane Glycoproteins IIb and IIIa

By Akikazu Hiraiwa, Akio Matsukage, Hiroshi Shiku, Toshitada Takahashi, Kazuyuki Naito, and Kazumasa Yamada

The glycoprotein (GP) IIb-IIIa complex was isolated from human platelet membranes by immunoaffinity chromatography using a monoclonal antibody specific for GP IIb-IIIa. GP IIb and IIIa were further separated in the presence of sodium dodecyl sulfate (SDS) by gel filtration high-performance liquid chromatography (HPLC). Two cycles of this procedure yielded almost complete separation of homogeneous preparations of GP IIb and IIIa. Each protein was then digested with lysyl endopeptidase (*Achromobacter* protease I), which cleaves at the carboxyl side of lysine

residues, and the resulting oligopeptides from GP IIb and IIIa were fractionated with HPLC using a C18 reverse-phase column. Comparison of the elution profiles showed no obvious homology between the two proteins. Amino acid sequences of selected oligopeptides from each glycoprotein were determined using a gas-phase protein sequencer. Sixty amino acid residues (26 residues for IIb and 34 residues for IIIa) were identified.

© 1987 by Grune & Stratton, Inc.

GLYCOPROTEINS (GP) IIb and IIIa are major constituents of the platelet plasma membrane and serve as the cellular receptor for fibrinogen.¹⁻⁹ Abnormalities of the GP IIb-IIIa complex result in failure of platelet aggregation. For example, patients with Glanzmann's thrombasthenia have either a deficiency of GP IIb-IIIa or abnormal molecules.^{9,10} In an unreduced state, GP IIb and GP IIIa have mol wt of 140,000 and 95,000, respectively, and they are present as a Ca²⁺-dependent heterodimer complex in both solubilized platelet extracts and in the plasma membrane of intact platelets.^{11,12} Despite the similarity of the amino acid composition of GP IIb and GP IIIa,^{13,14} tyrosyl tryptic peptide maps of these proteins are dissimilar.^{13,15,16}

Murine monoclonal antibodies specific for the GP IIb-IIIa complex inhibit both fibrinogen binding and platelet aggregation.¹⁷⁻²¹ In this study, we used a newly prepared murine monoclonal antibody (designated HPL-1), which recognizes GP IIb-IIIa and inhibits platelet aggregation induced by adenosine diphosphate (ADP), collagen, and a number of other physiological agents.²²⁻²⁴ GP IIb and IIIa were copurified by immunoaffinity chromatography with HPL-1 and then separated from each other by gel filtration high-performance liquid chromatography (HPLC).²⁶ Each purified GP was digested with lysyl endopeptidase. The resulting HPLC-generated oligopeptide maps and partial

amino acid sequence analysis showed no evidence of similarity between the two proteins.

MATERIALS AND METHODS

Production and purification of a monoclonal antibody. The production and specificity of the murine monoclonal antibody HPL-1 (IgG₁) used in this study have been described in detail elsewhere.²²⁻²⁴ In brief, this hybridoma was derived from (BALB/c × C57BL/6) female mice immunized with human platelets. By immunoprecipitation experiments with ¹²⁵I-labeled platelet lysates, HPL-1 precipitated the antigen molecules of 127 and 104 kd under reduced conditions and antigen molecules of 138 and 90 kd under unreduced conditions. This antibody inhibited platelet aggregation induced by ADP or collagen and did not react with platelets of thrombasthenia patients. Thus, the antigen recognized by HPL-1 antibody was considered the GP IIb-IIIa complex. HPL-1 was purified from ascites fluid by precipitation with saturated ammonium sulfate followed by diethylaminoethanol (DEAE) cellulose column chromatography.¹⁰ The purified antibody was dialyzed against coupling buffer (borate buffer pH 8.3 containing 0.5 mol/L of NaCl).

Immunoaffinity purification of the GP IIb-IIIa complex. Ten milligrams of purified HPL-1 antibody was coupled to 2 mL of cyanogen bromide-activated Sepharose 4B (Pharmacia Fine Chemicals, Piscataway, NJ) according to the manufacturer's directions. Platelets (5×10^{10}) were washed three times in phosphate-buffered saline (PBS) pH 7.4, containing 2.5 mmol/L of EDTA; whole platelets were then solubilized in 50 mL of extraction buffer (10 mmol/L of Tris-HCl, pH 7.4, 0.15 mol/L of NaCl, 1 mmol/L of phenylmethylsulfonyl fluoride (PMSF), 2.5 mmol/L of EDTA, and 0.5% Lubrol PX) for 45 minutes at 0 to 4 °C with periodic vortexing. An additional 50 mL of the extraction buffer was added, and the sample was incubated for another 30 minutes to permit complete solubilization. The lysate was centrifuged at 100,000 g for 30 minutes at 4 °C to remove particulate matter, and the supernatants containing platelet membrane protein were pooled. The platelet lysate was first applied to a column made of bovine serum albumin (BSA)-conjugated Sepharose 4B and equilibrated in 10 mmol/L of Tris-HCl, pH 7.4, 0.15 mol/L of NaCl, and 0.5% Lubrol. The throughout fraction, from which materials adsorbed nonspecifically to Sepharose and/or BSA had been removed, was applied to a HPL-1-Sepharose 4B affinity column (2 mL) equilibrated with the same buffer as described above. The column was washed extensively with a high-salt buffer (10 mmol/L of Tris-HCl, pH 7.4, 1 mol/L of NaCl and 0.5% Lubrol), and the retained protein was eluted with 50 mmol/L of diethylamine, pH 11.5, containing 0.1% Lubrol. The eluate was immediately neutralized by the addition of 200 µL of 2 mol/L of Tris-HCl, pH 7.2, and stored until further use at -80 °C. Protein concentration was determined using the Bio-Rad (Richmond, CA) Protein Assay kit.

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Approximately 20 to 30 μ g of the purified protein was electrophoresed in an 8% polyacrylamide slab gel according to the method of Laemmli.²⁵ Reduced samples contained 5% β -mercaptoethanol. Gels were stained with Coomassie brilliant blue. The following proteins were electrophoresed as mol wt standards: *Escherichia coli* RNA polymerase containing subunits of β' (160,000), β (150,000), σ (90,000), α (40,000); BSA (67,000).

Separation of glycoproteins IIb and IIIa by gel filtration HPLC. The affinity-purified GP IIb-IIIa complex was concentrated by lyophilization and then redissolved in water containing 1 mmol/L of EDTA and 0.1% SDS. The mixture was warmed for 60 minutes at 37 °C to achieve complete solubilization of protein complexes. To dissociate and purify the individual glycoproteins, the sample was applied to HPLC (Spectra-Physics, San Jose, CA) using a 60-cm TSK 4000SW gel filtration column equilibrated in 50 mmol/L of Tris-HCl, pH 7.2, 1 mmol/L of EDTA, and 0.1% SDS as described by Newman and colleagues.²⁶ Chromatography was performed at a flow rate of 0.5 mL/min, and the protein was monitored by measuring the absorbance at 280 nm. Peak fractions containing GP IIb or GP IIIa were collected separately. Each fraction was rechromatographed under conditions of the first chromatography to achieve homogeneous preparations of each GP. Fractions were pooled and lyophilized.

Removal of SDS from GP IIb and GP IIIa preparations after gel filtration HPLC. Although nonionic detergents such as NP-40 or Lubrol do not inhibit proteolytic digestion, SDS affects the proteinase activity of lysyl endopeptidase. Therefore, removal of SDS from protein samples was necessary prior to enzymatic digestion of GP IIb and GP IIIa. To achieve complete extraction of SDS, we used the method described by Henderson and co-workers.²⁷ In brief, the extraction solvent was a freshly prepared mixture of anhydrous acetone:triethylamine:acetic acid:water (85:5:5:5; vol/vol/vol/vol). Lyophilized GP IIb and GP IIIa samples containing SDS were dissolved directly in 1 mL of the extraction solvent containing 1 μ g of lysyl endopeptidase.²⁸⁻³⁰ The solution was kept at -20 °C for at least 1 hour. The proteins were precipitated by centrifugation (5,500 g for 45 minutes at -5 °C). The enzyme and the substrate were coprecipitated in this way to give a subsequent more reproducible digestion.³¹ To insure complete removal of SDS, the protein precipitate was washed twice with fresh extraction solvent. Finally, the precipitate was washed twice with acetone to remove traces of the extraction solvent. Residual acetone was removed by lyophilization.

Digestion of GP IIb and GP IIIa polypeptides with lysyl endopeptidase. The SDS-free lyophilized samples were each redissolved in 500 μ L of 50 mmol/L of Tris-HCl, pH 9.2, 0.1% Lubrol. An additional 1 μ g of lysyl endopeptidase was added to each sample. The mixtures were incubated at 37 °C for 24 hours and then lyophilized. Lysyl endopeptidase (*Achromobacter* protease I, Wako, Japan) is a proteolytic enzyme from *A. lyticus* M 497-1.²⁸⁻³⁰ This enzyme hydrolyzes peptide bonds at the carboxyl side of lysine residues in a manner similar to that of trypsin. This enzyme attacks the Lys-Pro bond, which is resistant to trypsin, and does not attack the arginyl bond, which is easily hydrolyzed by trypsin. Moreover, this enzyme also cleaves aminoethyl cysteine-X bonds.

Purification and sequencing of oligopeptides digested with lysyl endopeptidase. Oligopeptides were fractionated by HPLC on a 4 $\times$ 250-mm reverse-phase (RP) column (Synchropak RPP C18 column, pore size 300 Å, Synchrom, Linden, IN). The peptides were eluted with a linear gradient of 0% to 45% acetonitrile containing 0.1% trifluoroacetic acid at a flow rate of 0.7 mL/min for 120 minutes. Absorbance at 214 nm was monitored, and peaks were collected manually. Fractions obtained in this manner were not rechromatographed because they were already pure for subsequent analysis even after one cycle of chromatography. Oligopeptides

eluted as sharp peaks from RP-HPLC were selected as samples for amino acid sequencing because broad peaks occasionally contained two oligopeptides. Selected samples were lyophilized, and their amino acid sequences were determined on an Applied Biosystems (Foster, CA) Model 470A protein sequencer according to published procedures.^{32,33} Phenylthiohydantoin (PTH) amino acids were analyzed by RP-HPLC.

RESULTS

Isolation of the platelet membrane GP IIb-IIIa complex. The GP IIb-IIIa complex was purified from solubilized human platelets by chromatography on HPL-1-Sepharose 4B. Typical yields of the GP IIb-IIIa complex were ~500 μ g/10¹⁰ platelets. SDS-PAGE analysis of the immunoaffinity purified materials is shown in Fig 1A. The apparent mol wt of isolated GP IIb under unreduced and reduced conditions was 137,000 and 116,000, respectively; that of isolated GP IIIa under unreduced and reduced conditions was 90,000 and 100,000, respectively. These variations of apparent sizes of GP IIb and IIIa are in agreement with their previously reported behaviors.^{10,20} Densitometry scans of Coomassie brilliant blue-stained gels showed that GP IIb and IIIa at this stage were ~80% pure.

Separation of GP IIb and GP IIIa proteins. Although GP IIb and IIIa form a calcium-dependent heterodimer complex even in the presence of nonionic detergents, they can be dissociated with SDS and EDTA. Therefore, gel filtration HPLC was performed using a solution containing 0.1% SDS and 1 mmol/L of EDTA. As seen in Fig 2A, two GPs were well separated under the conditions used. Each protein peak was collected separately and rechromatographed to achieve complete purification (Fig 2B and C). SDS-PAGE indicated that the two proteins were separated from each other under these conditions and purified to apparent homogeneity (Fig 1B).

Proteolytic digestion of the GP IIb and GP IIIa polypeptides. After removal of SDS by solvent extraction, GP IIb and GP IIIa were digested with lysyl endopeptidase. The resulting oligopeptides were fractionated by RP-HPLC, and the peak fractions identified by ultraviolet (UV) absorbance were collected for subsequent amino acid sequence analysis. Repeated analysis of the peptide mapping gave the same result. As shown in Fig 3, the oligopeptide maps of these two glycoproteins appeared to be clearly different, confirming and extending previous observations^{13,15,16} of structural differences between GP IIb and GP IIIa.

Amino acid sequence analysis. The N-terminal amino acid sequences of several oligopeptides were determined using a gas-phase protein sequencer. The results are shown in Table 1. We obtained amino acid sequences identical to those of oligopeptides IIIa-3 that had been prepared independently. Therefore, we consider our analytical system reliable. Sixty amino acid residues (26 residues for IIb and 34 residues for IIIa) were identified.

DISCUSSION

During the last several years, much evidence derived from a number of laboratories³⁻⁸ has demonstrated that the human platelet GP IIb-IIIa complex serves as the receptor for

Fig 1. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) of human platelet membrane glycoproteins GP IIb and GP IIIa. Electrophoresis was performed with 8% polyacrylamide slab gel. Gels were stained with Coomassie brilliant blue. Samples used were: (A) protein eluate from HPL-1 monoclonal antibody-coupled Sepharose 4B, unreduced (lane 1) and reduced (lane 2); (B) separated GP IIb (lane 1, reduced) and GP IIIa (lane 2, reduced) after two cycles of gel filtration high-performance liquid chromatography as described in Fig 2.

extracellular fibrinogen, a plasma protein required for platelet aggregation. GP IIb consists of two disulfide-linked subunits, GP IIb α (mol wt 116,000) and GP IIb β (mol wt 23,000). In contrast, GP IIIa consists of a single polypeptide chain with multiple intrachain disulfide bonds (mol wt 105,000 as determined from SDS gels).³⁴

Several different procedures for purifying the mixture of the two GPs have been reported. Copurification of these GPs has been reported by McEver and co-workers,¹⁰ using a monoclonal antibody affinity column; by Leung and co-workers,¹⁵ using *Lens culinaris* lectin affinity chromatography; and by Jennings and Phillips,¹⁴ using sucrose density

gradient centrifugation and Sephacryl S-300 gel filtration chromatography. The determination of the amino acid sequence of a polypeptide requires a large quantity of highly purified protein samples. Immunoaffinity chromatography using specific monoclonal antibodies is often well suited for the initial stages of purification. As shown in Fig 1A, however, the immunoaffinity purified GP IIb-IIIa complex was contaminated with a small amount of actin, which may interact with GP IIb-IIIa.³⁵ Furthermore, antibodies that are directed against only one component of the GP IIb-IIIa complex can copurify both glycoproteins.¹⁰ Therefore, fur-

Fig 2. Separation of GP IIb from GP IIIa by gel filtration high-performance liquid chromatography. Sample was applied to a TSK-4000SW gel filtration column and chromatographed in the presence of sodium dodecyl sulfate (SDS) and EDTA at a flow rate of 0.5 mL/min. Absorbance was monitored at 280 nm, attenuated to 0.4 absorbance units full scale. (A) The first cycle chromatography of GP IIb-IIIa sample contained ~400 μ g of the protein. (B) Rechromatography of the GP IIb fraction of the first cycle. (C) Rechromatography of the GP IIIa fraction of the first cycle.

Fig 3. Reverse-phase high-performance liquid chromatography separation of the lysyl endopeptidase digested glycoproteins GP IIb and GP IIIa. As described in the Materials and Methods section, each glycoprotein was treated with lysyl endopeptidase and the resulting oligopeptides were chromatographed. Absorbance was monitored at 214 nm, attenuated to 0.1 absorbance units full scale. The oligopeptides indicated by the numbers IIb-1, IIb-2, IIIa-1, IIIa-2, and IIIa-3 were used for amino acid sequencing, the results of which are shown in Table 1.

*As in the case of IIIa-3, repeated analysis gave the same conclusion.

†Analysis for serine and threonine could not be accurately measured due to the presence of multiple peaks obtained during analysis of the phenylthiohydantoin (PTH) amino acids. Some of those peaks are known to reflect derivatives from serine and threonine, which were specifically detected as peaks at the different positions from other PTH amino acids.

ther separation and purification are necessary for the structural analysis of these components.

We evaluated several different protocols for the separation of GP IIb from GP IIIa, including electrophoretic elution from polyacrylamide gel slices containing GP IIb or GP IIIa,¹⁵ proteolytic digestion of proteins within gel pieces¹⁶ and, finally, gel filtration HPLC.²⁶ Although electroelution or proteolytic digestion of gel slices resulted in relatively low protein yields, two cycles of gel filtration HPLC achieved both good separation of GP IIb from GP IIIa and high protein recovery. The purity of the proteins isolated by this technique provided us with the opportunity to obtain large amounts of these two membrane glycoproteins for further study.

Because small amounts of SDS in the purified glycoprotein samples interfered significantly with subsequent proteolytic digestion, we removed SDS by a method of ion-pair extraction²⁷ that resulted in reproducible digestion. Because removal of SDS from a sample may cause protein aggregation, Lubrol was added to the sample to prevent aggregation.

Nonionic detergents such as NP-40, Lubrol, etc, did not affect the enzymatic digestion.

Computerized analysis of the autoradiograms of the two-dimensional tryptic ¹²⁵I peptide maps has indicated structural differences between GP IIb and GP IIIa.^{15,16} McEver and colleagues¹³ also demonstrated similar findings when comparing HPLC tryptic peptide maps of a mixture of ¹²⁵I-IIb and ¹³¹I-IIIa. These findings are in agreement with the peptide maps of the individual glycoproteins obtained following digestion with lysyl endopeptidase. Because we did not use radioiodinated glycoproteins in these experiments, our results represent information about all oligopeptides, including those that contain no tyrosine residues. Purified oligopeptides were then successfully used as samples for amino acid sequencing. Together, our results are consistent with the hypothesis that GP IIb and GP IIIa are coded for by different structural genes that are coordinately expressed.

Amino acid sequences of the five peptides obtained in this study were compared with 7,687 protein sequences in the Protein Research Foundation/Sequence Data Base (PRF/SEQDB)³⁶ to check for homology with other proteins. The computer search against all known protein sequences failed to reveal any significant similarity to the peptides derived from either GP IIb or GP IIIa.

The isolation of cDNA clones encoding GP IIb and GP IIIa should provide important additional insights about the structure of the human platelet fibrinogen receptor and the mechanism of regulation of its expression. A recent report documents the isolation of a λ phage containing a 20-kilobase (kb) genomic library, which, on transfection, leads to the expression of the α chain of the OKM-1, LFA-1, and platelet GP IIb-IIIa molecules.³⁷ Recently, a number of investigators were also successful in the isolation of mRNA species that encode human platelet GP IIb and IIIa.³⁸ Studies are in progress in our laboratory to isolate mRNA from a megakaryoblastic leukemia cell line that expresses these glycoproteins and to establish a cDNA library. Several amino acid sequences obtained in this study have regions suitable for the synthesis of oligonucleotide probes. Probes such as these should be useful for the screening of this cDNA library.

ACKNOWLEDGMENT

We would like to thank Drs Tadashi Hirata and Kazuo Yamaguchi (Kyowa Hakkō Kogyo, Tokyo) for their excellent technical advice concerning amino acid sequencing and Dr Yasuhiko Seto (Peptide Institute, Osaka) for analysis of sequence homology. The expert technical assistance of Yoshio Nishimoto (Aichi Cancer Center, Nagoya) and Saiko Kuroda (National Nagoya Hospital, Nagoya) is gratefully acknowledged. We also thank Dr Toshimitsu Niwa (Nagoya University, Nagoya) for his valuable suggestions, Atsuko Nagata for typing the manuscript, and Dr Howard L. Hosick for his critical reading of the manuscript.

Prothrombin Tokushima: Characterization of Dysfunctional Thrombin Derived From a Variant of Human Prothrombin

By Takashi Inomoto, Akira Shirakami, Shigenori Kawauchi, Toshio Shigekiyo, Shiro Saito, Kazuo Miyoshi, Takashi Morita, and Sadaaki Iwanaga

A mutant prothrombin, designated prothrombin Tokushima, was purified from plasma of a proband with 12% of normal plasma clotting activity and 42% of normal prothrombin antigen. The purified preparation gave a single band with the same mobility as that of "prothrombin" by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The factor Xa-catalyzed proteolysis of prothrombin Tokushima examined by SDS-PAGE was found to be identical to that of "prothrombin." Subsequently thrombin Tokushima was prepared by CM-Sepharose CL-6B column chromatography after prothrombin activation by factor Xa. The molecular weight of thrombin Tokushima estimated by SDS-PAGE was identical to that of "thrombin." Thrombin Tokushima exhibited less than 22% of normal clotting activity, and the value of k_{cat}/K_m ($\mu\text{mol}/$

$\text{L}^{-1} \text{second}^{-1}$) was less than one tenth of that of "thrombin" when Boc-Val-Pro-Arg-4-methylcoumaryl-7-amide was used as a substrate. However, active site titration using *p*-nitrophenyl-*p*'-guanidinobenzoate failed to detect any difference between the two. Thrombin Tokushima was 2.5% as effective as "thrombin" in inducing platelet aggregation. Interaction of thrombin Tokushima with antithrombin III was much slower than "thrombin" when followed by SDS-PAGE. Based on the residual thrombin activity, it was 33% as effective as "thrombin" in forming a complex with antithrombin III. These results indicate that the molecular defect resides in the thrombin portion of prothrombin Tokushima and that the binding sites for various substrates appear to be greatly impaired.

© 1987 by Grune & Stratton, Inc.

CONGENITAL dysprothrombinemia is a rare coagulation disorder. Only 16 variants have been reported,¹⁻¹⁷ all of them being characterized by a decrease in the functional level of prothrombin relative to antigenic level of prothrombin. Five of the prothrombin variants thus far identified have been purified and characterized. In the case of prothrombin Barcelona² and prothrombin Madrid,⁸ the functional defect has been shown to be a specific impairment of one of the two factor Xa-catalyzed cleavages, whereas in the case of prothrombin Quick,⁶ prothrombin Metz,⁹ and prothrombin Salakta,¹⁷ the defect is confined to the thrombin portion of the molecule. In 1983 we reported the first case of dysprothrombinemia in Japan as prothrombin Tokushima.^{13,14} The maternal and paternal sides have heterozygotes, respectively, for dysprothrombinemia and hypoprothrombinemia. The proband was a double heterozygote for prothrombin Tokushima and hypoprothrombinemia and therefore synthesized only the abnormal molecule. In this paper the physicochemical and enzymatic properties of prothrombin Tokushima are presented. These results demonstrate that prothrombin Tokushima is a new variant having an abnormality in the thrombin portion of the molecule.

MATERIALS AND METHODS

Blood was collected from the proband using plastic syringes that contained 1/10 volume of 3.8% trisodium citrate. Platelet-poor plasma of the proband with 12% of the clotting activity and 42% of "prothrombin" antigen was obtained after centrifugation and stored at -80°C .

Purification of prothrombin and thrombin. Prothrombin Tokushima and human "prothrombin" were purified according to the method of Morrison and Esnouf¹⁸ with slight modifications. Purified prothrombin (206 $\mu\text{g}/\text{mL}$ in 0.05 mol/L Tris-HCl, pH 8.0, containing 0.1 mol/L NaCl and 0.01 mol/L CaCl_2) was activated by bovine factor Xa (2.6 $\mu\text{g}/\text{mL}$) in the presence of bovine factor Va (28 $\mu\text{g}/\text{mL}$) and rabbit brain cephalin (100 $\mu\text{g}/\text{mL}$) for ten minutes at 37°C . Factor Xa was isolated as previously described.¹⁹ The resulting thrombin was isolated by chromatography on a CM-Sepharose CL-6B column according to Kawabata et al.²⁰ The activation mixture was applied to the column, previously equilibrated with 0.05

mol/L sodium phosphate, pH 6.5, and thrombin was eluted with a linear NaCl gradient (0 to 0.7 mol/L NaCl) in the same buffer.

Titration of thrombin with *p*-nitrophenyl-*p*'-guanidinobenzoate · HCl (*p*-NPGB). The titration of thrombin with *p*-NPGB (Nutritional Biochemicals, Cleveland, OH) was performed by the method of Chase and Shaw.²¹ Immediate burst of *p*-nitrophenol produced by the stoichiometric reaction of the catalytic site of thrombin with *p*-NPGB was monitored at 410 nm with a Hitachi 220A recording spectrophotometer (Tokyo). Thrombin active site concentration was determined using a molar extinction coefficient of 16,595 for *p*-nitrophenol at pH 8.3.

Kinetic experiments. Kinetic constants were determined using *t*-butyloxy-carbonyl-Val-Pro-Arg-4-methylcoumaryl-7-amide (Boc-Val-Pro-Arg-MCA) as the thrombin substrate (Peptide Institute, Osaka, Japan). The fluorescence of 7-amino-4-methylcoumarin (AMC) liberated from Boc-Val-Pro-Arg-MCA was monitored by a Hitachi fluorescence spectrophotometer (model 650-10S) equipped with a recorder. Emission at 440 nm was measured ($\lambda_{\text{ex}} = 380 \text{ nm}$ band pass 2 nm at 37°C). The reaction was performed at 37°C in 1 mL of 0.05 mol/L Tris-HCl (pH 8.0) containing 0.15 mol/L NaCl and 1 mmol/L CaCl_2 . The kinetic constants were calculated by the direct-linear plot based on the procedure of Cornish-Bowden.²²

Activation of factor XIII. Human placenta factor XIII was purchased from Hoechst Japan (Tokyo). The activity of factor XIII

was measured by a modified method of the monodansylcadaverine (Sigma Chemical, St. Louis) incorporation assay.²³

Platelet aggregation. Blood was collected from a normal donor into plastic tubes containing 1/10 volume of 3.8% trisodium citrate and 25 $\mu\text{g/mL}$ apyrase (Sigma Chemical). Platelets were subsequently isolated by gel filtration on a Sepharose 2B column equilibrated with Tyrode's buffer containing 3.5 mg/mL bovine serum albumin. Aggregation studies were performed in an aggregometer (Rikadenki Kogyo, Tokyo) on 500 μL of gel-filtered platelets (10^8 cells/mL) following addition of 39 μL of thrombin solution at the final concentrations of 1.1×10^{-9} mol/L to 4.0×10^{-8} mol/L.

Interaction with antithrombin III. Purified human antithrombin III was obtained from Boehringerwerke (Marburg, West Germany). Thrombin or thrombin Tokushima was incubated at 25 °C in twofold excess relative to antithrombin III in 0.05 mol/L Tris-HCl (pH 8.0)/0.1 mol/L NaCl. Serial aliquots were removed for SDS-PAGE and for residual thrombin activity measurements. Protein concentrations were determined by absorbance measurement at 280 nm. Molecular weight (72,000) and extinction coefficient ($E_{280}^{1\%} = 13.8$) were assumed to be the same for "prothrombin" and prothrombin Tokushima. Molecular weight (36,800) and extinction coefficient ($E_{280}^{1\%} = 18.3$) were also assumed to be the same for thrombins.

SDS-PAGE (8% polyacrylamide gel) in the presence and absence of 2-mercaptoethanol was performed by the method of Weber and Osborn.²⁴ The gels were stained with Coomassie brilliant blue R-250.

RESULTS

Properties of the purified prothrombin Tokushima. Since prothrombin Tokushima was totally adsorbed onto barium citrate,^{13,14} the usual technique for prothrombin purification was employed to isolate the mutant molecule. A single peak containing prothrombin Tokushima was eluted from a DEAE-Sephadex A-50 column at the same ionic strength as that observed for "prothrombin." However, the yield of prothrombin Tokushima was about half that of "prothrombin" (data not shown). Both preparations

Fig 1. Generation of the thrombin activity upon activation of "prothrombin" and prothrombin Tokushima by bovine factor Xa. Sixty-two micrograms each of "prothrombin" (●) and prothrombin Tokushima (○) were incubated at 37 °C with 0.8 μg of factor Xa, 8.4 μg of bovine factor Va, and 30 μg of rabbit brain cephalin in 0.3 mL of 0.05 mol/L Tris-HCl (pH 8.0) containing 0.1 mol/L NaCl and 0.01 mol/L CaCl_2 . The generated thrombin was measured by the fibrinogen clotting assay at selected intervals until reaching a plateau. The clotting activity of α -thrombin was determined using purified human fibrinogen (approximately 95% clottable). A reference curve was prepared using NIH standard thrombin (lot B3).

Fig 2. Factor Xa-catalyzed proteolysis of "prothrombin" and prothrombin Tokushima. The activation of each prothrombin was performed under the same conditions as described in Fig 1. After incubation at 37 °C for varying time periods, 50 μL aliquots were removed for SDS-PAGE. Prothrombin, α -thrombin, fragment 1, fragment 2, B chain, and A chain are abbreviated, respectively, as P, T, F1, F2, Bch and Ach.

migrated as a single band with the same mobility of SDS-PAGE, and their molecular weights were estimated as 72,000.

Activation of purified "prothrombin" by factor Xa in the presence of factor Va, phospholipids and Ca^{2+} produced thrombin with a specific activity of 1300 NIH U/mg after five minutes incubation. However, as shown in Fig 1, the thrombin activity produced from prothrombin Tokushima reached a plateau with about 21% of the normal level after 10 minutes.

The cleavage patterns of prothrombin by factor Xa on SDS-PAGE indicated that the proteolysis of prothrombin Tokushima was indistinguishable with that of "prothrombin," yielding thrombin, fragment 1 and fragment 2, with the molecular weights identical to those of the normal counterparts (Fig 2). Moreover, upon reduction thrombin Tokushima yielded B chain and A chain with the same molecular weight as those found in " α -thrombin." These results suggest that the cleavage sites of prothrombin Tokushima by factor Xa are normal and that the defect apparently resides in the molecule in the thrombin portion.

Preparation of the purified thrombin Tokushima. Thrombin Tokushima was prepared by CM-Sepharose CL-6B column chromatography after prothrombin activation by factor Xa, as described in Materials and Methods. As shown in Fig 3, thrombin Tokushima eluted as single peak at the same ionic strength as that observed for " α -thrombin." Figure 4 shows the SDS-PAGE patterns of thrombins thus purified. The molecular weight of the reduced and unreduced forms of thrombin Tokushima appeared indistinguishable from that of " α -thrombin."

Enzymatic properties of thrombin Tokushima. Active site titration studies using *p*-NPGb revealed that thrombin Tokushima possessed the same catalytic activity as " α -thrombin." As shown in Table 1, 95.7% of the catalytic sites in thrombin Tokushima was titratable with *p*-NPGb. On the other hand, kinetic analysis for the hydrolysis of Boc-Val-Pro-Arg-MCA by thrombin Tokushima yielded a higher K_m , a lower k_{cat} , and a lower k_{cat}/K_m ratio than that of " α -thrombin." The fibrinogen clotting activity of thrombin Tokushima was 525 NIH U/mg corresponding to 21.5% of

Fig. 3. CM-Sepharose CL-6B column chromatography of "α-thrombin" (A) and thrombin Tokushima (B). "Prothrombin" (1.76 mg) and prothrombin Tokushima (1.68 mg) were activated separately as described in "Methods," and the reaction mixture was applied to the column. After elution of the first peak containing fragments 1 and 2, thrombin was eluted with a 0 to 0.7 mol/L NaCl gradient in 0.05 mol/L sodium phosphate buffer, pH 6.5. Protein concentration was measured by absorbance at 280 nm (—), and the thrombin clotting activity (---) and the molarity of NaCl (·····) are shown.

normal, although it was 69.9% as effective as "α-thrombin" in the activation of factor XIII.

Figure 5 shows the thrombin-induced platelet aggregation by "α-thrombin" and thrombin Tokushima. At an enzyme concentration of 2×10^{-9} mol/L, rapid aggregation was observed with "α-thrombin," whereas no aggregation was induced by thrombin Tokushima at comparable concentration. Based on the amount of enzyme required to give an equivalent incomplete aggregation, thrombin Tokushima was less than 3% as effective as "α-thrombin."

Figure 6A shows SDS-PAGE analysis of the thrombin-antithrombin III interaction. When an excess molar ratio of "α-thrombin" to antithrombin III was employed, the band of antithrombin III disappeared within ten minutes incubation, and a high molecular weight complex I, probably consisting of a 1:1 enzyme:inhibitor stoichiometric complex, appeared on SDS-PAGE. After incubation for 30 minutes, complex II, which has been attributed to partially degraded complex,²⁵ was observed. When thrombin Tokushima and antithrombin III were incubated under identical conditions, only a small amount of complex I was formed after ten minutes. Following incubation for 30 minutes, the amount of complex I

increased, while no complex II was observed. These results suggest a decreased rate in the formation of the thrombin-antithrombin III complex, and little, if any, degradation of this complex with thrombin Tokushima, as compared to that of "α-thrombin." Figure 6B shows the time course of thrombin inhibition by antithrombin III in the absence of heparin. In both cases a time-dependent inhibition of the thrombin activity was observed. After ten minutes incubation the residual activity of "α-thrombin" reached a plateau with 45% of the initial activity, and thrombin Tokushima was inhibited by antithrombin III at a slower rate than that of "α-thrombin." Based on the residual thrombin activity after one minute incubation with antithrombin III, thrombin Tokushima was one third as effective as "α-thrombin" in forming the enzyme: inhibitor complex. A summary of these results is presented in Table 2.

DISCUSSION

Reports of congenital dysprothrombinemia have amounted to 16 families, which can be divided into three groups in terms of the localization of the functional defect within the molecule. The first group, typified by prothrombin San Juan,³ has an abnormality in the fragment 1-2 region of the molecule. The second group, which includes prothrombin Barcelona² and prothrombin Madrid,⁸ shows abnormalities in the sites cleaved by factor Xa. In the third group the thrombin portion of the molecule is abnormal, and examples of this group include prothrombin Quick,⁶ prothrombin Metz,⁹ and prothrombin Salakta.¹⁷

Fig. 4. Analysis of purified thrombins by SDS-PAGE. α-Thrombin, B chain, and A chain are abbreviated, respectively, as T, Bch, and Ach.

Table 1. Comparison of the Kinetic Parameters of "α-Thrombin" and Thrombin Tokushima

Titration with p-NPGB (%)	α-Thrombin 100	Thrombin Tokushima 95.7
Kinetic constants*		
K _m (μmol/L)	12.0	94.5
k _{cat} (sec ⁻¹)	93.5	49.4
k _{cat} /K _m (μmol/L ⁻¹ s ⁻¹)	7.79	0.52

*Kinetic constants were determined at 37 °C in 1 mL of 0.05 mol/L Tris-HCl (pH 8.0) containing 0.15 mol/L NaCl and 1 mmol/L CaCl₂.

Fig 5. Thrombin-induced aggregation of gel-filtered platelets. Platelet concentration was 10^8 /mL in Tyrode's buffer. Thrombin Tokushima or " α -thrombin" was added at the final concentration indicated.

As we reported previously, prothrombin Tokushima is quantitatively adsorbed onto barium citrate, and the immunoelectrophoretic pattern of this prothrombin in plasma also appears to be normal.^{13,14} Moreover, the proteolytic processing of prothrombin Tokushima by factor Xa is indistinguishable from "prothrombin," as shown in this report. However, the prothrombin assay in plasma using the procoagulant fraction of *Echis carinatus* venom²⁶ and staphylocoagulase²⁷ as activating agents demonstrated only a small percentage of

Table 2. Summary of the Relative Activity (%) of Thrombin Tokushima with " α -Thrombin"

Fibrinogen	21.5
Factor XIII activation	69.9
Platelet aggregation	2.5
Antithrombin III inhibition	33.3

the normal clotting activity (data not shown). These observations suggest that the defect of prothrombin Tokushima may result from altered catalytic properties of the resulting thrombin. This prompted us to isolate thrombin produced upon activation of purified prothrombin Tokushima, and to characterize further its catalytic properties in a purified system.

Abnormal properties of thrombin Tokushima are observed in its kinetic parameter. The values of K_m and k_{cat} of thrombin Tokushima for Boc-Val-Pro-Arg-MCA are both abnormal, indicating that it differs from " α -thrombin" not only by its affinity for the substrate but also by its catalytic efficiency. The active-site titration value of thrombin Tokushima using *p*-NPGB is the same as that of " α -thrombin," suggesting that the residues that comprise the catalytic triad must be normal. These enzymatic properties are different from those of thrombin Quick⁶ and thrombin Metz.⁹ The active site titration of thrombin Metz using dansylarginine-*N*-(3-ethyl-1,5-pentanediol) amide (DAPA) has revealed that the fluorescence enhancement is only 34% of the maximum fluorescence observed with " α -thrombin," suggesting an abnormality of the catalytic site. Thrombin Quick has also been reported to have similar properties to those of thrombin Metz.

Thrombin Tokushima has no apparent platelet-aggregating activity at a concentration of 2×10^{-9} mol/L. However, at higher concentration of thrombin Tokushima (4×10^{-8} mol/L), incomplete aggregation of platelets was observed. In thrombin-mediated platelet activation, the catalytic site of thrombin and its binding site with platelets are both essential for this process. Concerning the thrombin-binding site in platelets, both high-affinity binding site ($K_d = 1.5 \times 10^{-9}$ mol/L) and low-affinity binding site ($K_d = 3 \times 10^{-7}$ mol/L) have been reported.²⁸ The decreased activity of thrombin Tokushima in initiating platelet aggregation in all likelihood reflects its reduced affinity to the high-affinity binding site in platelet, since titration of thrombin Tokushima with *p*-NPGB reveals a normal catalytic site.

Complex formation between antithrombin III and thrombin Tokushima also occurs at a slow rate in comparison to " α -thrombin." In addition, degradation of this complex is significantly less, indicating an abnormality of thrombin Tokushima in its interaction with antithrombin III.

In conclusion, the activities of thrombin Tokushima on synthetic tripeptide substrate, fibrinogen, factor XIII, platelets, and antithrombin III are reduced when compared with " α -thrombin," while active site titration with *p*-NPGB shows a normal value. Thus, in thrombin Tokushima the catalytic triad, consisting of the residues with His-43, Asp-99, and Ser-205 of the thrombin B chain,²⁹ seems to be structurally intact, but other residues in the vicinity of the catalytic site, eg, apolar binding sites,²⁹ may be structurally abnormal.

Fig 6. Inhibition of thrombin by antithrombin III, " α -thrombin" or thrombin Tokushima (1×10^{-6} mol/L) was incubated with antithrombin III (5×10^{-7}) in 0.05 mol/L Tris-HCl (pH 8.0) containing 0.1 mol/L NaCl. Serial aliquots (60 μ L) were removed for SDS-PAGE. (A) Antithrombin III (1.9 μ g), " α -thrombin" (2.2 μ g) and thrombin Tokushima (2.2 μ g) were applied to gels. (B) The remaining thrombin clotting activity was measured under the same conditions as described for Fig 1. The results are given in percentage of the initial thrombin activity v incubation time. Thrombin Tokushima (○) and " α -thrombin" (●).

ACKNOWLEDGMENT

We are indebted to Dr C. T. Esmon (Thrombosis/Hematology Research Program, Oklahoma Medical Research Foundation, Oklahoma City), for kindly providing bovine factor Va. We thank Dr Kisiel (Department of Pathology and Biochemistry, University of New Mexico, Albuquerque) for his help in preparing the English manuscript. We thank Mizumo Akiyoshi for her expert secretarial assistance.

A Murine Antiglycoprotein Ib Complex Monoclonal Antibody, SZ 2, Inhibits Platelet Aggregation Induced by Both Ristocetin and Collagen

By Changgeng Ruan, Xiaoping Du, Xiaodong Xi, Peter A. Castaldi, and Michael C. Berndt

A new monoclonal antibody (MoAb), SZ 2, reactive with the human platelet glycoprotein Ib complex has been produced by the hybridoma technique. SZ 2 immunoprecipitated the components of the glycoprotein Ib complex, glycoprotein Ib and glycoprotein IX, from Triton-X-100-solubilized, periodate-labeled platelets. Western blot analysis indicated that the epitope for SZ 2 was on the α -subunit of glycoprotein Ib. Scatchard analysis of SZ 2 binding to formaldehyde-fixed, washed platelets revealed a single class of binding sites with $K_d = 6.6 \pm 3.3 \times 10^{-10}$ mol/L and $15,200 \pm 4,100$ binding sites per platelet (mean $\pm$ SD, $n = 10$). Intact antibody and its purified (Fab')₂ fragments not only inhibited the ristocetin-dependent binding of von Willebrand factor to platelets and ristocetin-induced platelet agglutination but also inhibited platelet aggregation induced by Type I collagen and platelet-activating factor (PAF). SZ 2 inhibited platelet serotonin and β -thromboglobulin release in response to these stimuli

and also platelet thromboxane A₂ formation in response to ristocetin and collagen. SZ 2 was without effect on platelet aggregation or release in response to other platelet stimuli such as ADP, thrombin, or arachidonic acid. The inhibition by SZ 2 of collagen- and PAF-induced platelet aggregation is surprising in that Bernard-Soulier syndrome platelets, which lack the glycoprotein Ib complex, respond normally to both these stimuli. SZ 2 was unreactive toward Bernard-Soulier syndrome platelets, as evaluated by fluorescence-associated cell sorting, and had no effect on the collagen- and PAF-induced aggregation of Bernard-Soulier syndrome platelets. The combined results suggest that the inhibition by SZ 2 of collagen- and PAF-induced aggregation of normal platelets is steric and are consistent with the glycoprotein Ib complex and the platelet collagen and PAF receptor(s) being adjacent in the human platelet plasma membrane.

IN RESPONSE to vascular injury, the initial event in hemostasis involves the adhesion of platelets to collagenous and noncollagenous elements in the exposed subendothelium.^{1,2} At high shear flow, in capillaries and the microvasculature, both plasma von Willebrand factor and von Willebrand factor incorporated in the vessel wall subendothelial matrix play an important role in platelet adherence.^{3,4} At low shear rate in aorta and large blood vessels, platelet adhesion occurs independently of von Willebrand factor^{3,5} and presumably involves the direct adhesion of platelets to fibrils of collagen. There is now convincing evidence that the platelet membrane glycoprotein Ib complex is the receptor involved in the von Willebrand factor-dependent adhesion of platelets to exposed vascular subendothelium.⁶ Bernard-

Soulier syndrome platelets, which lack the components of the glycoprotein Ib complex,⁷ fail to bind von Willebrand factor,⁸ to agglutinate in the presence of ristocetin,^{9,10} and to adhere normally to subendothelium.⁵ The glycoprotein Ib complex is a heterodimer complex and contains both glycoprotein Ib and glycoprotein IX.¹¹ On SDS-polyacrylamide gels, glycoprotein Ib has an apparent molecular weight of 170,000 and consists of two disulfide-linked subunits, Ib_a and Ib_b, with apparent molecular weights of 135,000 and 25,000, respectively. Glycoprotein IX has an apparent molecular weight of 22,000 under both nonreducing and reducing conditions.¹¹ The binding domain for von Willebrand factor appears to be present on the α -subunit of glycoprotein Ib.^{6,12} The available evidence suggests that the glycoprotein Ib complex does not play an important role in platelet-collagen interaction. Bernard-Soulier syndrome platelets aggregate normally in response to collagen.¹³ Further, the murine monoclonal antibody (MoAb), AN 51, directed against the α -subunit of glycoprotein Ib,¹⁴ blocks ristocetin-induced, von Willebrand factor-dependent platelet agglutination but has no effect on platelet aggregation induced by types I or III collagen fibrils.¹⁵ In this study we describe a new murine MoAb, SZ 2, directed against the α -subunit of glycoprotein Ib, which not only inhibits ristocetin-induced, von Willebrand factor-dependent platelet agglutination but also collagen-induced and platelet-activating factor (PAF)-induced platelet aggregation. The combined data are consistent with the platelet glycoprotein Ib complex, the platelet collagen receptor, and the platelet PAF receptor being sterically adjacent in the human platelet plasma membrane.

MATERIALS AND METHODS

Materials. Bovine serum albumin (Fraction V), adenosine diphosphate, hypoxanthine, aminopterin, thymidine, A 23187, platelet-activating factor, and arachidonic acid were purchased from Sigma, St. Louis; sodium periodate (Univar) from Ajax Chemicals, Sydney, Australia; pristane from Aldrich, Milwaukee, WI; polyethylene glycol 4000 from Merck, Darmstadt, West Germany; ristocetin sulfate from Lundbeck, Copenhagen, Denmark; epinephrine

from Wuxi No. 4 Pharmaceutical Plant, Wuxi, China; equine tendon collagen from Horm, Munich, West Germany; bovine von Willebrand factor from Speywood, England; bovine α -thrombin from Biochemical Products, Tianjing, China; RPMI 1640 medium from Gibco, Grand Island, NY; pepsin from Worthington, Freehold, NJ; protein-A-Sepharose CL-4B from Pharmacia, Sydney, Australia; Na ^{125} I from New England Nuclear, Boston; and ^{3} H-sodium borohydride from Amersham, Sydney, Australia. Platelet-activating factor (PAF), type I calf skin collagen, and human α -thrombin were the generous gifts of Dr Vargaftig, Paris; Dr Y. Legrand, Paris; and Dr J. W. Fenton, II, Albany, NY, respectively. Fluorescein-tagged goat antimouse IgG was from Cappel, Philadelphia; peroxidase-conjugated goat antimouse IgG was from Kirkegaard and Perry Laboratories, Gaithersburg, MD. Human von Willebrand factor was purified from commercial Factor VIII concentrate (CNTS, Paris, France) essentially as previously described¹⁶ and labeled by lactoperoxidase-catalysed radioiodination.

Platelet preparation and labeling. Platelet preparation from freshly drawn blood, platelet washing, and the periodate-labeling of platelets were each performed as previously described.¹⁷ For fluorescence-associated cell sorting and the analysis of SZ 2 binding to platelets, the platelets were washed and then fixed with 1% (wt/vol) paraformaldehyde essentially as previously described.¹⁵ Blood was also obtained from two patients, RS and LS, with the Bernard-Soulier syndrome.⁷ Platelets were isolated from these patients essentially as previously described.⁷

Monoclonal antibodies. The SZ 2 antibody (IgG₁) was prepared according to the method of Kochler and Milstein¹⁸ using 8-week-old BALB/C mice and washed platelets as the immunogen. Clones were assessed for antibody secretion into supernatant culture fluid by radioimmunoassay (RIA) using ^{125} I-labeled affinity-purified rabbit antimouse IgG and washed platelets essentially according to our previously described method.¹¹ Selected hybridomas were grown to confluence in 2-mL Costar plates and subsequently in 25-cm² plastic flasks. Cloning was performed by the limiting dilution method using 96-well microtitre plates with mouse peritoneal macrophage feeder layers. For SZ 2 this procedure was repeated a total of six times, prior to injection (10^7 cells) intraperitoneally (IP) into BALB/C mice previously primed with 0.5 mL of pristane. Resulting ascitic fluid was drained, centrifuged, and stored at -20°C .

IgG was purified from SZ 2 ascites fluid by chromatography on protein-A-Sepharose CL-4B as described by Ey et al.¹⁹ and was dialysed against either 0.01 mol/L sodium phosphate, 0.15 mol/L sodium chloride, pH 7.4 (PBS buffer) or 0.01 mol/L Tris, 0.15 mol/L sodium chloride, pH 7.4 prior to storage at -20°C . The purified IgG gave a single band at $\approx 150,000$ molecular weight as assessed by SDS-polyacrylamide gel electrophoresis under nonreducing conditions. SZ 2 (Fab')₂ fragments were prepared from SZ 2 IgG by pepsin digestion as described by Collier.²⁰ On SDS-polyacrylamide gel electrophoresis under nonreducing conditions, the SZ 2 (Fab')₂ gave a single band with a molecular weight of $\approx 100,000$. SZ 2 IgG was radioiodinated by the chloramine T method; $>95\%$ of the incorporated radioactivity was precipitable by 10% (wt/vol) trichloroacetic acid. Other MoAbs against the human platelet glycoprotein Ib complex have been previously reported: FMC 25 (IgG₁)^{11,14}; AN 51 (IgG₁)^{14,21}; WM 23 (IgG₁)¹¹; and AP 1.²² AP 1 was the generous gift of Dr T. J. Kunicki, Milwaukee. In some experiments SZ 21 (IgG₁) and WM 17 (IgG_{2b}) directed against the human platelet glycoprotein IIb/IIIa complex and FMC 18 (IgG₁) directed against an antigen on *Toxoplasma gondii*²³ were used as negative controls. IgG was purified from these MoAbs by chromatography on protein-A-Sepharose CL-4B essentially as described above.

Aggregation studies. The effect of MoAb IgG or (Fab')₂ fragments on platelet aggregation response was evaluated essentially as

previously described.¹⁴ Platelet aggregation was followed in PRP (3×10^8 platelets/mL, final concentration) stirred at 1,000 rpm at 37°C using either a Payton (Scarborough, Ontario) lumiaggregometer (model 1000) or a PAM-2 aggregometer (Danyang, China). Monoclonal antibody IgG (10 to 50 $\mu\text{g/mL}$, final concentration) or (Fab')₂ fragments (10 $\mu\text{g/mL}$) were added three minutes before the addition of stimuli at the following final concentrations: ADP, 2 $\mu\text{mol/L}$; epinephrine, 2.5 $\mu\text{mol/L}$; type I calf skin collagen, 10 to 20 $\mu\text{g/mL}$; equine tendon collagen, 0.5 to 1 $\mu\text{g/mL}$; ristocetin, 1.25 mg/mL; bovine vWF, 0.75 U/mL; A23187, 16 $\mu\text{mol/L}$; PAF, 0.3 $\mu\text{mol/L}$; and arachidonic acid, 200 $\mu\text{g/mL}$. Platelet aggregation in response to α -thrombin was performed using washed platelets suspended in Tyrode's solution (3×10^8 platelets/mL, final concentration); human α -thrombin, 0.05 to 0.1 U/mL; bovine α -thrombin, 0.125 U/mL). To evaluate platelet release the contents of the aggregometer cuvette were centrifuged five minutes after the addition of the platelet stimulus. Released serotonin was measured using the fluorescence method of Curzon et al.²⁴ β -Thromboglobulin was measured by RIA (the β -thromboglobulin assay kit was supplied by Shanghai 2nd Medical College, Shanghai, China). The formation of thromboxane B₂ was measured according to the procedure of Fitzpatrick,²⁵ using an iodinated tracer of thromboxane B₂. The anti-thromboxane B₂ antibody used for this assay was the generous gift of Dr J. Maclof (Unité 150 INSERM, Hôpital Lariboisière, Paris).

Inhibition of binding of von Willebrand factor to platelets. Binding of von Willebrand factor (vWF) to washed platelets was determined as previously described¹⁵ with minor modification. The binding assay for ^{125} I-labeled vWF to platelets was performed at room temperature in a final volume of 0.25 mL. Each tube contained 200 μL of washed platelets (2×10^8), 20 μL of PBS buffer or MoAb IgG (10 to 40 $\mu\text{g/mL}$, final concentration) in PBS buffer, 20 μL of ^{125} I-labeled vWF (25,000 cpm, 10 $\mu\text{g/mL}$ final concentration), and 10 μL of ristocetin (1 mg/mL, final concentration). After 30 minutes duplicate 100- μL aliquots of the reaction mixture were overlaid on 50 μL of dibutyl phthalate/dioctyl phthalate (2:1) in a narrow bore eppendorf tube and centrifuged at 12,000 g for three minutes. After careful aspiration of the supernatant, the pellet was counted for radioactivity in a gamma counter. Control experiments with this assay system confirmed that $>95\%$ of the binding of ^{125} I-labeled vWF to platelets was ristocetin-dependent.

Monoclonal antibody binding to platelets. Binding of SZ 2 IgG to formaldehyde-fixed, washed human platelets was assessed by equilibrium saturation analysis of ^{125} I-labeled SZ 2 IgG binding essentially as described by Powell-Jones et al.²⁶ Preliminary experiments established that equilibrium binding of SZ 2 IgG to platelets was achieved within 30 minutes under the assay conditions and remained at a constant level until 60 minutes. For the equilibrium saturation analysis of binding, 0.01 to 100 $\mu\text{g/mL}$, final concentration, of unlabeled SZ 2 IgG in PBS buffer was mixed with 10,000 cpm of ^{125} I-labeled SZ 2 in the same buffer and added to the platelet suspension (10^7 platelets/tube; in PBS buffer containing 0.3% (wt/vol) bovine serum albumin). The final volume was 200 μL /tube. After incubation at 37°C for 60 minutes, the platelets were separated by centrifugation, washed briefly in PBS buffer containing 0.1% (wt/vol) bovine serum albumin, and the pellet counted for radioactivity in a gamma counter. Control experiments confirmed that no dissociation of bound SZ 2 occurred within the time period of the platelet washing step. Nonspecific binding under the assay condition was $<2\%$. Binding data was analyzed according to the method of Scatchard.²⁷ The effect of a 100-fold excess of the antiglycoprotein Ib complex MoAbs, FMC 25, WM 23, AN 51, and AP 1, on the equilibrium binding of SZ 2 to platelets was performed using platelet-rich plasma prepared from venous blood collected into 3.2% sodium citrate as anticoagulant essentially as described by Collier et al.²⁰

Platelet immunofluorescence and examination by flow cytometry. Normal or Bernard-Soulier syndrome platelets (0.5 to 1.0×10^5) were incubated with saturating concentrations of SZ 2 IgG or WM 17 IgG at 20°C for ten minutes with intermittent agitation and then washed twice with Hanks' buffered saline solution (HBSS) containing 8 mmol/L potassium EDTA. As a control, first layer MoAb was substituted with an "irrelevant" MoAb, FMC 18, which reacts only with *T. gondii*. The washed platelets were then incubated with fluorescein-conjugated goat antimouse IgG (previously optimized for titre) at 20°C for ten minutes and then washed twice as described above. The amount of platelet-bound antibody was analyzed on a FACS 440 flow cytometer (Becton Dickinson, Mountain View, CA) using an argon ion laser at 488 nm and 200 mW and a $530 \pm 15\text{ nm}$ bandpass filter for log fluorescence determination. Data was stored and analyzed as LIST-mode files on a Becton Dickinson Consort 40 computer essentially as described by Adelman et al.²⁸

Immunoprecipitation. Immunoprecipitation using the mouse MoAb, SZ 2, employed the Triton X-100 lysate of periodate-labeled platelets and was performed as previously described.^{11,14} A mouse MoAb, WM 21, directed against human CALLA, was used as the negative control.

Electrophoresis. SDS-polyacrylamide gel electrophoresis, protein staining, fluorography, western blot analysis, and crossed immunoelectrophoresis were all performed as previously described.^{11,14}

RESULTS

Immune studies: Demonstration that SZ 2 is directed against the human platelet glycoprotein Ib complex. Immunization of mice with washed human platelets led to the establishment of a number of hybridoma cell lines secreting MoAbs to human platelets. One of these MoAbs, SZ 2, proved to be of special interest and was the subject of further detailed studies. The results of immunoprecipitation experiments using Triton-X-100-solubilized, periodate-labeled platelets are shown in Fig 1. SZ 2 immunoprecipitated the

Fig 1. Fluorography of an exponential 5% to 20% SDS-polyacrylamide gel run under nonreduced (lanes 1 through 3) and reduced conditions (lanes 4 through 6) of the WM 21 and SZ 2 immunoprecipitates derived from the Triton X-100 lysate of periodate-labeled platelets; lanes 2 and 5, WM 21 immunoprecipitate; lanes 3 and 6, SZ 2 immunoprecipitate. Molecular weight markers in order of decreasing molecular weight are myosin ($200,000$), β -galactosidase ($130,000$), phosphorylase b ($94,000$), bovine serum albumin ($68,000$), ovalbumin ($43,000$), carbonic anhydrase ($29,000$), soybean trypsin inhibitor ($21,000$), and lysozyme ($14,000$).

components of the glycoprotein Ib complex (Fig 1 lane 3—nonreduced; lane 6—reduced). The glycoprotein assignments are based on the apparent molecular weights under nonreducing and reducing conditions¹¹ and their correspondence to the platelet glycoprotein profile in the platelet lysate: glycoprotein Ib, nonreduced mol wt = $170,000$, reduced mol wt = $135,000$ and $25,000$, most intensely labeled glycoprotein by the sialic-acid-specific periodate labeling procedure²⁹; glycoprotein IX, nonreduced and reduced mol wt = $22,000$. In addition, SZ 2 gave the same immunoprecipitation pattern when directly compared with other defined antiglycoprotein Ib complex MoAbs, FMC 25, WM 23, AN 51, and AP 1 (data not shown) and the same pattern of minor bands previously observed in immunoprecipitation experiments with FMC 25, AN 51, and quinine/quinidine drug-dependent antibodies.¹⁴ These comprise two minor bands of slightly lower apparent molecular weight than glycoprotein Ib in the nonreduced gel (lane 3) and a band of slightly higher molecular weight than glycoprotein Ib (lane 3) and glycoprotein Ib_a (lane 6) in the nonreduced and reduced gels, respectively. As previously discussed in detail,¹⁴ these bands probably derive from partial reduction of glycoprotein Ib and the co-precipitation of glycoprotein Ia with the glycoprotein Ib complex.

Since both the glycoprotein Ib complex and glycoprotein Ia co-immunoprecipitate with antiglycoprotein Ib complex MoAbs,^{14,20,30} presumably because of their mutual association with actin-binding protein,^{31,32} western blot analysis and crossed immunoelectrophoresis were performed to further characterize the reactivity of SZ 2. By western blot analysis, SZ 2 reacted with a single protein band of molecular weight $170,000$, nonreduced, and $135,000$, reduced (Fig 2), consis-

Fig 2. Western blot of SDS-polyacrylamide-gel-separated human platelet proteins probed with SZ 2. The experiment was performed as described under Materials and Methods. Molecular weight markers in order of decreasing molecular weight are myosin ($200,000$), β -galactosidase ($130,000$), phosphorylase b ($94,000$), bovine serum albumin ($68,000$), ovalbumin ($43,000$), carbonic anhydrase ($29,000$), and soybean trypsin inhibitor ($21,000$).

tent with SZ 2 recognizing an epitope on the α -chain of glycoprotein Ib. In contrast, glycoprotein Ia has an apparent molecular weight of 153,000 under nonreducing conditions and 167,000 under reducing conditions.³³ The reactivity of SZ 2 was further assessed by performing crossed immunoelectrophoresis with polyspecific rabbit antihuman platelet antisera and by incorporating radioiodinated SZ 2 IgG or WM 23 IgG in the intermediate gel in the second dimension. On autoradiography, SZ 2 gave an equivalent pattern to that observed with the antiglycoprotein Ib complex MoAb, WM 23.¹¹ There was no binding in the region of the gel previously shown to contain the immunoprecipitation arc for glycoprotein Ia³³ (data not shown).

Binding of ¹²⁵I-SZ 2 to fixed, washed platelets was rapid, being $\approx 50\%$ complete within ≈ 5 minutes and reached saturation within 30 minutes. Figure 3 shows the relationship between the amount of SZ 2 added and the amount bound. Binding of SZ 2 reached saturation with $\approx 0.3 \mu\text{g}$ of SZ 2 bound per 10^8 platelets. Scatchard analysis revealed a single class of binding sites (Fig 3) with $K_d = 6.6 \pm 3.3 \times 10^{-10}$ mol/L and $15,200 \pm 4,100$ binding sites per platelet (mean $\pm$ SD, $n = 10$). The results are comparable with the number of binding sites determined under identical conditions for the antiglycoprotein Ib complex MoAb, AN 51: $12,800 \pm 3,000$ (mean $\pm$ SD, $n = 10$)³⁴ and similar to the number of binding sites found for other antiglycoprotein Ib complex MoAbs with platelets in platelet-rich plasma.^{11,20} The binding of ¹²⁵I-SZ 2 ($1 \mu\text{g}/\text{mL}$) to platelets in platelet-rich plasma ($10^8/\text{mL}$) was inhibited by $>98\%$ by a 100-fold excess of unlabeled SZ 2, by $\approx 35\%$ by $100 \mu\text{g}/\text{mL}$ of AP 1, by $\approx 25\%$ by $100 \mu\text{g}/\text{mL}$ of AN 51, and by $<10\%$ by $100 \mu\text{g}/\text{mL}$ of WM 23 or FMC 25 (data not shown), indicating that SZ 2 bound to a unique epitope on the glycoprotein Ib complex relative to the other antiglycoprotein Ib complex MoAbs.

Effect of SZ 2 on platelet function. SZ 2 IgG (10 to $50 \mu\text{g}/\text{mL}$) had no effect on platelet aggregation induced by adenosine diphosphate, ADP ($2 \mu\text{mol}/\text{L}$), epinephrine ($2.5 \mu\text{mol}/\text{L}$), calcium ionophore, A23187 ($16 \mu\text{mol}/\text{L}$), arachidonic acid ($200 \mu\text{g}/\text{mL}$), human α -thrombin (0.05 to $0.1 \text{ U}/\text{mL}$), or bovine α -thrombin ($0.125 \text{ U}/\text{mL}$) (data not shown). In contrast, SZ 2 IgG ($10 \mu\text{g}/\text{mL}$) was a potent inhibitor of ristocetin-induced, von Willebrand factor-depen-

Fig 3. Effect of increasing concentration of ¹²⁵I-labeled SZ 2 on its steady-state binding to formaldehyde-fixed platelets. The insert shows a Scatchard plot of the same data with the $K_d \approx 4.4 \times 10^{-10}$ mol/L and the maximum number of sites $\approx 1.3 \times 10^4$ /platelet. The binding analysis was performed as described under Materials and Methods.

dent platelet agglutination (Fig 4A) and bovine von Willebrand factor-dependent platelet agglutination (Fig 4B). SZ 2 IgG directly inhibited ristocetin-induced platelet agglutination, since at saturating concentrations it blocked the ristocetin-dependent binding of human von Willebrand factor to washed human platelets by $\approx 80\%$. In this regard, it was less effective than AN 51 IgG, which completely blocked ristocetin-dependent von Willebrand factor binding under the same conditions (data not shown). SZ 21, directed against the human platelet glycoprotein IIb/IIIa complex, inhibited ristocetin-dependent von Willebrand factor binding by $<20\%$ (data not shown). Unexpectedly, SZ 2 IgG ($10 \mu\text{g}/\text{mL}$) was also a potent inhibitor of platelet aggregation induced by type I calf skin collagen ($20 \mu\text{g}/\text{mL}$) (Fig 4C) and by platelet-activating factor, PAF ($0.3 \mu\text{mol}/\text{L}$) (Fig 4D). SZ 2 IgG (10 to $50 \mu\text{g}/\text{mL}$) was also a strong inhibitor of platelet aggregation induced by the more potent collagen stimulus, equine tendon collagen (0.5 to $1.0 \mu\text{g}/\text{mL}$) (data not shown, cf Fig 6). Higher concentrations of equine tendon collagen (2 to $10 \mu\text{g}/\text{mL}$) partially overcame the inhibitory effect of SZ 2 IgG. However, the lag time before the onset of platelet shape change and aggregation was always increased in the presence of SZ 2 IgG, and the rate of aggregation was always slower than the rate in the absence of SZ 2. Since there is some evidence that the platelet Fc-receptor and the glycoprotein Ib complex may be sterically related in the human platelet membrane,³⁵ the aggregation experiments were repeated with SZ 2 (Fab')₂ fragments to eliminate the possibility that the Fc-region of the mouse immunoglobulin had a compounding effect on the observed results. The SZ 2 (Fab')₂ fragments, however, at $10 \mu\text{g}/\text{mL}$ gave similar inhibitory effects with respect to the intact immunoglobulin for platelet aggregation induced by ristocetin, by type I calf skin collagen, and by PAF (Fig 4). Early events in platelet activation in response to ristocetin, collagen, and PAF as defined by the platelet release reaction (Table 1) and thromboxane B₂ formation (Table 2) were also inhibited by SZ 2 IgG. In contrast, SZ 2 IgG had little or no effect on the release reaction or thromboxane B₂ formation in response to

Fig 4. Effect of SZ 2 and its (Fab')₂ fragments on platelet aggregation. Trace 1, buffer control; trace 2, $10 \mu\text{g}/\text{mL}$ SZ 2; trace 3, $10 \mu\text{g}/\text{mL}$ SZ 2 (Fab')₂ fragments. Panel A, ristocetin ($1.25 \text{ mg}/\text{mL}$); panel B, bovine von Willebrand factor ($0.75 \text{ U}/\text{mL}$); panel C, type I calf skin collagen ($20 \mu\text{g}/\text{mL}$); panel D, platelet activating factor ($0.3 \mu\text{mol}/\text{L}$). The platelets were pre-incubated with buffer, SZ 2, or SZ 2 (Fab')₂ fragments for three minutes before the addition of the appropriate stimulus.

Table 1. Inhibition (%) of Platelet Function by SZ 2 IgG

Stimulus	Serotonin Release (% Inhibition)	β -Thromboglobulin Release (% Inhibition)
Ristocetin (1.25 mg/mL)	85	78
Collagen (20 μ g/mL)	72	47
PAF (0.3 μ mol/L)	73	78
Thrombin (1 U/mL)	< 10	< 10
Arachidonic Acid (200 μ g/mL)	< 10	< 10

Platelet-rich plasma or washed platelets were pre-incubated with SZ 2 IgG (10 μ g/mL), final concentration at 37 °C for three minutes before the addition of the appropriate stimulus. Measurement of serotonin and β -thromboglobulin release were as described under Materials and Methods. The results are the mean of three separate experiments.

α -thrombin or arachidonic acid. In addition, SZ 21, directed against the human platelet glycoprotein IIb/IIIa complex, had no significant effect on platelet thromboxane B_2 formation in response to either ristocetin or collagen (Table 2).

A series of experiments were also performed to contrast the effects of other antiglycoprotein Ib complex MoAbs (at 50 μ g/mL, final concentration) on platelet aggregation induced by ristocetin (1.5 mg/mL, final concentration), equine tendon collagen (1 μ g/mL, final concentration), PAF (0.1 μ mol/L), and ADP (5 μ mol/L). None of the antiglycoprotein Ib complex antibodies had any effect on ADP-induced platelet aggregation. Neither FMC 25 (epitope on glycoprotein IX)¹⁴ nor WM 23 (epitope on the α -chain of glycoprotein Ib)¹¹ inhibited platelet aggregation induced by either ristocetin or collagen. Consistent with the report of Ruan et al,¹⁵ AN 51 (epitope on the α -chain of glycoprotein Ib)¹⁴ completely inhibited ristocetin-induced, von Willebrand factor-dependent platelet agglutination but had no effect on collagen-induced platelet aggregation. Similar to SZ 2, AP 1 (epitope on the α -chain of glycoprotein Ib) also completely inhibited platelet aggregation induced by both ristocetin²² and collagen (data not shown). The inhibition of collagen-induced platelet aggregation by AP 1 was less pronounced at higher collagen concentrations in similar

Table 2. Effect of SZ 2 and SZ 21 on the Formation of Thromboxane B_2

Stimulus	Thromboxane B_2 (ng/3 $\times 10^6$ Platelets, $\pm$ SD)		
	Control	SZ 2 (10 μ g/mL)	SZ 21 (10 μ g/mL)
Arachidonic Acid (330 μ mol/L)	1210 $\pm$ 640	1060 $\pm$ 380	1610 $\pm$ 420
Thrombin (0.125 U/mL)	151 $\pm$ 68	169 $\pm$ 72	203 $\pm$ 95
Collagen (25 μ g/mL)	42 $\pm$ 15	9 $\pm$ 3*	30 $\pm$ 19
Ristocetin (1.25 mg/mL)	27 $\pm$ 13	9 $\pm$ 3*	22 $\pm$ 9

Platelet-rich plasma or washed platelets were pre-incubated with SZ 2 IgG or SZ 21 IgG at 37 °C for three minutes before the addition of the appropriate stimulus. Measurement of thromboxane B_2 formation was as described under Materials and Methods. The results are the mean of six separate experiments.

* $p < 0.01$ for SZ 2 IgG compared to buffer control or SZ 21 IgG by Student's t test.

manner to that observed with SZ 2. PAF-induced platelet aggregation was not inhibited by AN 51, WM 23, FMC 25, AP 1, or FMC 18 (directed against *T gondii*).

Effect of SZ 2 on Bernard-Soulier syndrome platelets. The inhibition by SZ 2 of collagen-induced aggregation is inexplicable in the sense that Bernard-Soulier syndrome platelets, which lack the components of the glycoprotein Ib complex,⁷ aggregate normally in response to collagen.¹³ There are two likely possibilities consistent with these results. One possibility is that SZ 2 is directed against an epitope present on more than one platelet surface membrane protein: SZ 2 could be directed against both the α -chain of glycoprotein Ib and a platelet collagen receptor. Alternatively, the inhibition of collagen-induced aggregation by SZ 2 could be steric with the binding of SZ 2 to the glycoprotein Ib complex affecting the normal interaction of collagen with a proximal collagen receptor. The first possibility seems unlikely since immunoprecipitation, western blot analysis, and crossed immunoelectrophoresis strongly suggest that SZ 2 is directed against an epitope present only on the glycoprotein Ib complex. Furthermore, another antiglycoprotein Ib complex antibody, AP 1, directed against a distinct epitope to SZ 2 on the glycoprotein Ib complex, was also found to inhibit collagen-induced platelet aggregation. To help further distinguish between these two possibilities we examined the reactivity of SZ 2 toward Bernard-Soulier syndrome platelets. The reactivity of SZ 2 toward normal and Bernard-Soulier syndrome platelets as evaluated by fluorescence-associated cell sorting is shown in Fig 5. The upper panels show the reactivity of normal and Bernard-Soulier syndrome platelets toward FMC 18, directed against *T gondii* and establish the negative controls for background fluorescence by this method. The middle panels show the reactivity of normal and Bernard-Soulier syndrome platelets toward WM 17, directed against the human platelet glycoprotein IIb/IIIa complex and establish the controls for positive platelet

Fig 5. Immunofluorescence profiles of normal (control) and Bernard-Soulier syndrome platelets (BSS) stained with FMC 18 (against *Toxoplasma gondii*), WM 17 (against glycoprotein IIb/IIIa), and SZ 2 (against glycoprotein Ib complex). Formaldehyde-fixed platelets incubated with the respective MoAb and fluorescein-labeled second antibody were analyzed by fluorescence flow cytometry. Each single parameter histogram, cell number ν log fluorescence (arbitrary units), was derived from the analysis of 10,000 platelets. The experimental procedure and data analysis were performed as described under "Materials and Methods."

immunofluorescence. Although SZ 2 was positive against normal platelets, the immunofluorescence seen with Bernard-Soulier syndrome platelets was indistinguishable from that observed with the negative control, confirming that SZ 2 was solely directed against an epitope present on the glycoprotein Ib complex. Furthermore, although SZ 2 inhibited collagen-induced platelet aggregation with control platelets, it was without effect on the collagen-induced aggregation of Bernard-Soulier syndrome platelets at any collagen concentration (Fig 6). The latter result strongly suggests that SZ 2 does not bind directly to a platelet-collagen receptor and supports the concept that the human platelet glycoprotein Ib complex and the platelet-collagen receptor are proximal in the human platelet membrane. Similar results were obtained with PAF-induced platelet aggregation. Although SZ 2 (50 $\mu\text{g}/\text{mL}$) was a potent inhibitor of the aggregation of normal platelets by PAF (40 nmol/L), SZ 2 had no effect on the PAF-induced aggregation of Bernard-Soulier syndrome platelets at any PAF concentration (data not shown).

DISCUSSION

In response to vascular injury, platelets rapidly adhere to the exposed vascular subendothelium.¹ At high shear flow, one adhesion mechanism appears to involve von Willebrand factor^{3,4} and a specific von Willebrand factor receptor on the human platelet membrane surface, the glycoprotein Ib complex.² For example, Bernard-Soulier syndrome platelets, which apparently genetically lack the components of the glycoprotein Ib complex, glycoprotein Ib and glycoprotein IX,⁷ fail to bind von Willebrand factor,⁸ to agglutinate in the presence of ristocetin,^{9,10} and to adhere normally to subendothelium at high shear flow.⁵ In recent years a number of antiglycoprotein Ib murine MoAbs have been described (AN 51,¹⁵ 6D1,²⁰ and AP 1²²) that block the ristocetin-dependent binding of von Willebrand factor to human platelets. The inhibition of von Willebrand factor binding to platelets correlates well with the failure of MoAb-treated platelets to agglutinate with ristocetin²⁰ or to adhere normally to exposed vascular subendothelium at high shear flow.¹⁵ In this study we have described a new murine MoAb, SZ 2, directed against an epitope on the α -subunit of glycoprotein Ib (Fig

2). Like the previously reported murine MoAbs, AN 51, 6D1, and AP 1, SZ 2 and its (Fab')₂ fragments were potent inhibitors of both ristocetin-induced, human von Willebrand factor-dependent and bovine von Willebrand factor-dependent platelet agglutination (Fig 4) and inhibited the ristocetin-dependent binding of human von Willebrand factor to platelets by $\approx 80\%$. SZ 2 had no effect on platelet aggregation induced by ADP, epinephrine, A23187, arachidonic acid, and by human or bovine α -thrombin. Unexpectedly, however, SZ 2 and its (Fab')₂ fragments were potent inhibitors of platelet aggregation induced by collagen and by PAF (Fig 4). SZ 2 appeared to interfere with an early event in collagen-platelet interaction. SZ 2 inhibited the platelet release reaction in response to collagen as measured by the extent of secretion of dense body serotonin or α -granule β -thromboglobulin (Table 1) and also inhibited the mobilization of arachidonic acid from platelet membrane phospholipid as measured by thromboxane B₂ formation (Table 2). With high concentrations of equine tendon collagen (2 to 10 $\mu\text{g}/\text{mL}$), SZ 2 consistently prolonged the lag time between the addition of the collagen fibrils and the onset of platelet shape change. Although there is some evidence that collagen-induced platelet aggregation may be partially von Willebrand factor-dependent at threshold concentrations of collagen,^{36,37} the inhibition of the binding of von Willebrand factor to platelets by SZ 2 is unlikely to represent the mechanism by which SZ 2 inhibits collagen-dependent platelet aggregation. AN 51, which completely blocks the binding of von Willebrand factor to platelets, has no effect on collagen-induced platelet aggregation (this study).¹⁵ Similarly, 3F8, a MoAb against human von Willebrand factor, completely blocks ristocetin-induced, human von Willebrand factor-dependent platelet agglutination¹⁶ but has no effect on collagen-induced platelet aggregation at collagen concentrations at which SZ 2 completely inhibits platelet aggregation (Berndt and Gregory, unpublished observations).

The inhibition of collagen-induced platelet aggregation by SZ 2 is surprising in the sense that Bernard-Soulier syndrome platelets, which lack the glycoprotein Ib complex, aggregate normally in response to collagen (this study, Fig 6).¹³ One possible explanation for this apparent discrepancy is that SZ 2 is directed against a binding site on more than one platelet membrane surface protein, ie, SZ 2 could be directed against an epitope present on a platelet collagen receptor as well as the platelet membrane glycoprotein Ib complex. The available evidence, however, is inconsistent, with this being the probable explanation for the observed results since detailed immunochemical analysis indicated that SZ 2 only recognized the glycoprotein Ib complex and since SZ 2 did not inhibit the collagen-induced aggregation of Bernard-Soulier syndrome platelets (Fig 6). An alternate possibility to explain the inhibition of collagen-induced aggregation by SZ 2 is that the glycoprotein Ib complex and the platelet collagen receptor are proximal in the platelet membrane, ie, the binding of SZ 2 or its (Fab')₂ fragments to the α -subunit of glycoprotein Ib sterically interferes with the normal interaction of collagen with an adjacent collagen receptor or membrane protein required for normal collagen-dependent platelet activation. There are three lines of evi-

Fig 6. Effect of FMC 18 and SZ 2 on the collagen-induced aggregation of control and Bernard-Soulier syndrome platelets. Control (3×10^8 platelets/mL, final concentration) and Bernard-Soulier syndrome platelets (1.5×10^8 platelets/mL) were pre-incubated with 50 $\mu\text{g}/\text{mL}$ of either FMC 18 IgG or SZ 2 IgG for three minutes prior to the addition of 1 $\mu\text{g}/\text{mL}$ (control) or 0.5 $\mu\text{g}/\text{mL}$ (Bernard-Soulier) of equine tendon collagen.

dence consistent with this possibility. First, consistent with the preliminary observations of Pidard et al,³⁸ AP 1, directed against a distinct epitope on the glycoprotein Ib complex from that of SZ 2 (since AP 1 and SZ 2 only partially crossblock), also inhibited collagen-induced platelet aggregation. Second, SZ 2 only inhibited collagen-induced platelet aggregation when bound to glycoprotein Ib, since SZ 2 had no effect on the collagen-induced aggregation of Bernard-Soulier syndrome platelets. A third line of evidence derives from the recent data of Nieuwenhuis et al³⁹ and of Fox.^{31,32} Nieuwenhuis et al have described a patient whose platelets failed to react with collagen and lacked a specific membrane protein, glycoprotein Ia. Fox has recently shown that in unstimulated platelets at least one subunit of the glycoprotein Ib complex spans the platelet membrane and is bound to a platelet membrane endoskeleton via actin-binding protein.^{31,32} Glycoprotein Ia also apparently spans the platelet membrane and, like glycoprotein Ib, is also bound to the platelet endoskeleton via actin-binding protein.^{31,32} These results suggest that glycoprotein Ia and the glycoprotein Ib complex may be normally associated in the human platelet membrane because of their mutual interaction with actin-binding protein and provide an explanation for the inhibition by SZ 2 of both ristocetin-induced, human von Willebrand factor-dependent platelet agglutination and collagen-induced platelet aggregation. Similar arguments apply for the inhibition of PAF-induced platelet aggregation by SZ 2. SZ 2 was found to be a potent inhibitor of both the PAF-induced platelet release reaction (Table 1) and PAF-induced platelet aggregation (Fig 4). However, Bernard-

Soulier syndrome platelets aggregated normally in response to platelet activating factor, and this aggregation was unaffected by SZ 2. This suggests that, similar to the glycoprotein Ib complex and the platelet collagen receptor, the glycoprotein Ib complex and the platelet PAF receptor (or a membrane protein required for normal PAF-dependent platelet activation) may also be proximal in the plane of the platelet membrane.

The combined evidence suggests that the antiglycoprotein Ib complex MoAb, SZ 2, inhibits platelet aggregation induced by both ristocetin and collagen because the platelet glycoprotein Ib complex and the platelet collagen receptor may be sterically adjacent in the human platelet plasma membrane. Houdijk et al have recently demonstrated that the adhesion of platelets to collagen substrata at high shear flow is von Willebrand factor-dependent.⁴⁰ It is interesting to speculate that the possible steric relationship between the platelet von Willebrand receptor and the platelet collagen receptor suggested by the current study may be relevant to these observations. Future studies should help resolve this question and help delineate the precise molecular role of glycoprotein Ia in collagen-induced platelet aggregation.

ACKNOWLEDGMENT

It is a pleasure to acknowledge the technical assistance of Cheryl Gregory, Arnold Kabral, William J. Booth, Peixia Li, and Zhaoyue Wang with some aspects of this work. We thank Athena Webster for her assistance in manuscript preparation and Peter Woods for his assistance in the preparation of the figures.

Human Erythroleukemia Cells Adhere to Fibronectin: Evidence for a M_r 190,000-Receptor Protein

By Ismo Virtanen, Jari Ylänné, and Tapio Vartio

Human erythroleukemia cells (K562) adhered rapidly on fibronectin (Fn)-coated growth substratum under serum-free conditions. The adhesion could be quantitatively inhibited by the synthetic peptide Arg-Gly-Asp-Ser (RGDS) and upon hemin-induced differentiation or trypsinization of the cells. Many of the cells also displayed rapid spreading that led to a redistribution of F-actin into spreading edges and in many cells also to a formation of typical actin fibers attaching to the ventral aspect of the cells. The spreading of the cells was inhibited by cytochalasin B but not by microtubule-disrupting drugs, suggesting an active role for the microfilament system in the spreading process. Direct overlay assay of electrophoretically separated polypep-

tides with ¹²⁵I-Fn showed that in K562 cells there is a major M_r 190,000 Fn-binding protein that is lost upon differentiation. A similar overlay assay with purified plasma and cellular Fns followed by immunostaining with anti-Fn antibodies revealed a reaction with a similar polypeptide. The binding of Fns on the nitrocellulose sheets could be inhibited and the bound Fn eluted by using the RGDS peptide. From octylglucoside extracts of radioactively surface-labeled cells, distinct M_r 190,000/185,000 membrane glycoproteins bound to Fn-heptapeptide-Sepharose, further suggesting that the M_r 190,000 polypeptide would be the Fn-receptor of the K562 cells.

© 1987 by Grune & Stratton, Inc.

MUCH INTEREST has been devoted to the mechanisms of fibronectin(Fn)-mediated adhesion of cells to culture substratum.¹ Results from several laboratories indicate that this process takes place via receptor-like proteins present in the surface membrane of diverse cells, including fibroblasts,²⁻⁶ macrophages,⁷ and platelets.⁸ In fibroblasts the receptor appears to be an M_r 140,000 polypeptide,^{2,6} whereas a distinct M_r 100,000 has been characterized in macrophages⁷ and an M_r 110,000 in platelets.⁸

Murine erythroleukemia (MEL) cells⁹⁻¹¹ and reticulocytes¹² also appear to exhibit an adhesion capacity to Fn-coated substrata and to cells that have Fn-matrix. This capacity appears to be lost upon dimethyl sulfoxide (DMSO)-induced differentiation of the MEL cells¹¹ as well as upon further maturation of the red blood cells.¹² Recently Patel and Lodish¹¹ suggested that an M_r 140,000 protein would be responsible for the Fn-binding of MEL cells and would thus be a candidate for "erythroid Fn-receptor." These results suggested to Patel and Lodish^{10,11} and Patel et al.¹² that Fn-mediated adhesion might play a role in the maturation of precursors of red blood cells. The results of the present study show that human K562 erythroleukemia cells both adhere and spread on exogenous Fn and express a distinct M_r 190,000 Fn-binding protein that may mediate this process.

MATERIALS AND METHODS

Cell lines and adhesion experiments. Human erythroleukemia K562¹³⁻¹⁵ cells were cultured in RPMI 1640 medium supplemented with 10% fetal calf serum (Flow Laboratories, Irvine, Scotland) and antibiotics.

Fibronectin (pFn) was purified from human plasma as described by Engvall and Ruoslahti.¹⁶ Multiwell dishes and Petri dishes (Nunc, Copenhagen, Denmark) were coated by pFn (20 µg mL⁻¹) for two hours. Then the dishes were washed with NaCl-P buffer (140 µmol/L NaCl, 10 µmol/L sodium phosphate, pH 7.4). Laminin from EHS sarcoma, used to coat culture dishes as above, was from Bethesda Research Laboratories (Gaithersburg, MD). Similar amounts of cells were plated in all experiments in serum-free RPMI medium. In some experiments the cells were induced to differentiate by exposing them to hemin (20 µmol/L; Sigma, St. Louis).¹⁷ The induced state was monitored by using both the benzidine staining for hemoglobin and monoclonal antibodies (MoAbs) binding to erythroid α- and β-spectrins (HE53DA7; Virtanen et al, in preparation) in immunoblotting (see below). Poly-L-lysine (20 µg mL⁻¹; Sigma) was used to adhere K562 cells nonspecifically in some experiments by preincubation of the coverslips one hour before plating of the cells. In some experiments the cells were exposed to trypsin (0.25%; Sigma) for 15 minutes before plating, to cytochalasin B (1 µg mL⁻¹; Sigma) or to demecolcine (1 µg mL⁻¹; Sigma) for one to 24 hours. The synthetic peptide Arg-Gly-Asp-Ser (RGDS, Peninsula Laboratories, Belmont, CA) was used for cell adhesion experiments at a concentration of 0.1 to 0.5 mg mL⁻¹ in serum-free RPMI medium.

SDS-PAGE and immunoblotting. Polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulphate (SDS-PAGE) was performed under reducing conditions according to Laemmli¹⁸ using 6.5% slab gels. Polypeptides were transferred onto nitrocellulose sheets according to Towbin et al.¹⁹ After the transfer the sheets were incubated overnight in a 3% bovine serum albumin-NaCl-P buffer and processed for overlay experiments (see below) or immunostaining. For immunostaining of the nitrocellulose sheets the following antibodies were used: monoclonal spectrin (HE53DA7) and Fn (against the cell-binding site; N295, Mallinkrodt, St. Louis) as well as polyclonal Fn antibodies. The sheets were exposed to the antibodies for 60 minutes, washed, and were then reacted with peroxidase-coupled rabbit antimouse or sheep antirabbit IgG antisera (Dakopatts, Glostrup, Denmark), respectively. After washing, the peroxidase reaction was developed as described by Towbin et al.¹⁹ The molecular weights were estimated by using the low molecular weight calibration kit (Pharmacia, Uppsala, Sweden) and in some experiments by using reduced pFn (M_r 220 000) and myosin (M_r 200 000) from bovine Purkinje fibers as additional standards.

Fn overlay and radioactive surface labeling experiments. For overlay experiments, fibronectin from human fibroblasts (cFn, Bethesda Research Laboratories, Gaithersburg, MD) was iodinated (^{125}I) by using the technique of Bolton and Hunter²¹ as modified.²² The reagent was from Radiochemical Centre, Amersham, UK. The overlay assay of nitrocellulose sheets was performed as described earlier for ^{125}I -cFn²³ and ^{125}I -calmodulin.²⁴

Alternatively, the nitrocellulose sheets were first exposed to purified pFn or cFn ($20\text{ }\mu\text{g mL}^{-1}$) for 60 minutes, washed, and were then exposed to monoclonal or polyclonal antibodies to Fn. After washing, the bound antibodies were detected by peroxidase immunostaining as above. In a set of experiments the RGDS synthetic peptide was applied on the sheets together with Fns at a concentration of 0.5 mg mL^{-1} to inhibit the binding of the proteins. The peptide was used also at the same concentration to elute bound Fns from the nitrocellulose sheets. For this purpose the peptide was applied on the sheet for 30 minutes.

For radioactive surface labeling, the neuraminidase-galactose oxidase-sodium borohydride technique was used.²⁵ After electrophoresis the gels were processed for fluorography.²⁶

Affinity-binding of cell surface glycoproteins to Fn-synthetic peptide-Sepharose. The synthetic heptapeptide, Gly-Arg-Gly-Asp-Ser-Pro-Cys (GRGDSPC), which corresponds to the cell-adhesion promoting region of Fn and which can autoinhibit Fn-function,²⁷ was purchased from Peninsula Laboratories. A portion (0.25 mg) of the peptide was coupled to 1.0 mL of wet, activated thiol-Sepharose (Pharmacia, Uppsala, Sweden) according to the manufacturer's instructions. For affinity binding experiments, surface-labeled K562 cells were extracted in 200 mmol/L octylglucoside (Sigma) in NaCl-P buffer, supplemented with 3 mmol/L phenylmethyl sulfonyl fluoride at 0°C for 30 minutes. Insoluble material was removed by centrifugation at $1400 \times g$ for 15 minutes. Aliquots of the extract were then applied on peptide-thiol-Sepharose for two hours in the presence or absence of the synthetic tetrapeptide RGDS (0.5 mg mL^{-1}).²⁸ Thereafter the Sepharose-beads were washed with the octylglucoside-buffer and the bound proteins were eluted with the electrophoresis sample buffer for analysis in SDS-PAGE.

Fluorescence microscopy. For fluorescence microscopy the cells on culture dishes or glass coverslips were fixed in 3.5% paraformaldehyde for five minutes. Then they were permeabilized in 0.01% NP40 and exposed to NBD-phalloidin (Molecular Probes, Junction City, OR), a fluorescent probe for F-actin.³⁰ In some experiments the cells were fixed in methanol, cooled to -20°C , and were then first exposed to mouse vinculin antiserum, raised against vinculin purified from chicken gizzards as described.³¹ Then the specimens were exposed to fluorescein isothiocyanate-coupled rabbit antimouse IgG antiserum (Cappel Laboratories, Cochranville, PA). A Zeiss Universal microscope, equipped with epiilluminator IIIRS, was used to examine the specimens.

RESULTS

When exponentially growing K562 cells were plated in serum-free medium on tissue culture wells, precoated with pFn, over 95% of the cells attached firmly within ten minutes (Fig 1A) and could not be detached even by vigorous shaking. Within one to two hours, over 30% of the adhered K562 cells displayed distinct flattening and spreading (Fig 1B). Pre-exposure of the cells to trypsin or plating in the presence of the synthetic peptide RGDS, the minimum cell-binding sequence of Fn,²⁶⁻²⁸ inhibited quantitatively the attachment of the cells on pFn-coated dishes. Furthermore, exposure of the cells to cytochalasin B completely prevented

Fig 1. Phase-contrast microscopy on adhesion and spreading of the K562 cells on Fn-coated growth substratum. Within ten minutes after plating, most of the cells were adhered (A), and over 30% of them showed distinct spreading within one to two hours (B). Original magnification $\times 200$.

the spreading but not the adhesion of the cells, whereas exposure to demecolcine did not have any apparent effect on these processes. In control experiments, only occasional cells bound to plain plastic substratum or on laminin-coated dishes, and all the cells could be brought into suspension by gentle agitation. Results from adhesion experiments on K562 cells under different culture conditions are summarized in Table 1.

In rounded K562 cells, labeling with NBD-phalloidin revealed an even rim-like surface staining (Fig 2A). In cells spreading on pFn, NBD-phalloidin gave a reaction with microspike- and lamellae-like structures at the spreading edges of the cells (Fig 2B). In the spread cells, distinct NBD-phalloidin-positive cytoplasmic fibrils were seen (Fig 2C), and antibodies to vinculin revealed related ventral membrane-associated plaques in the adhering cells (Fig 2D).

When K562 cells were induced to differentiate with hemin,¹⁷ they lost the ability to attach on pFn-coated substratum and remained floating in the medium. In immunoblotting of the electrophoretically separated polypeptides, the induced but not the control K562 cells showed a distinct doublet of spectrin polypeptides, as revealed with the MoAb HE53DA7 (Fig 3, lanes 5, 6).

We then studied putative receptor proteins for Fn in K562

Table 1. Adhesion and Spreading of K562 Cells on Different Substrata

Growth Substratum and Culture Condition	Cells Adhered (10 min)	Cells Spread (2 h)
20 $\mu\text{g mL}^{-1}$ pFn	95%	30%–35%
20 $\mu\text{g mL}^{-1}$ laminin	<5%*	0
plastics	<5%*	0
pFn + trypsinized cells	<5%*	0
pFn + RGDS	<5%*	0
pFn + hemin-induced cells	<5%*	0
pFn + cytochalasin B	95%	0
pFn + demecolcine	95%	30%–35%

Culture dishes were coated with the reagents indicated and the cells treated as described in the "Materials and Methods" section. The number of adhered or spread cells were calculated by visual inspection.

*Adhered cells could be brought into suspension by a gentle agitation.

cells by using direct overlay assays in which the polypeptides of the cells were first separated in SDS-PAGE and then transferred onto nitrocellulose sheets. Then the sheets were either exposed to ^{125}I -cFn and the bound protein was detected by autoradiography or the lanes were exposed to pFn or cFn and the bound proteins were detected by immunostaining. Using ^{125}I -cFn, a distinct ca M_r 190,000 polypeptide could be revealed in K562 cells (Fig 3, lane 2), whereas no binding proteins were detected in hemin-differentiated K562 cells (Fig 3, lane 4), which expressed erythroid α - and β -spectrins, as revealed by immunoblotting with a MoAb (Fig 3, lane 6). When unlabeled pFn or cFn were applied on the nitrocellulose sheets and their binding was detected, a prominent M_r 190,000 polypeptide could again be revealed in K562 cells with both monoclonal (Fig 4, lane 2, pFn; lane 3, cFn) and polyclonal Fn antibodies (Fig 4, lane 4, pFn). When the RGDS synthetic peptide was included in the overlay experi-

Fig 2. Localization of F-actin in control K562 cells adhered on poly-L-lysine-coated substratum (A), spreading cells 30 minutes after plating on pFn-coated dishes (B), and spread cells two hours after plating (C). Note the even cell surface-associated staining in (A), more bright staining of the spreading edges in (B), and the reaction with stress fibre-type of filaments in (C). In the spread cells, antibodies to vinculin visualize typical ventral plaques (D). Original magnification $\times 600$.

Fig 3. SDS-PAGE separated polypeptides of control K562 cells (lanes 1, 2, 5) and hemin-induced K562 cells (lanes 3, 4, 6) transferred onto nitrocellulose sheets and stained for protein, ^{1,3} exposed to ^{125}I -cFn (lanes 2, 4) or immunostained for α - and β -spectrins (lanes 5, 6). Note the distinct Fn-binding polypeptide in lane 2, lack of the reaction in lane 4, and two polypeptides at M_r 240,000 and 220,000 in lane 6. Molecular weights of the control proteins are indicated on the left.

Fig 4. SDS-PAGE separated polypeptides of K562 cells transferred onto nitrocellulose sheets and exposed to unlabeled Fns (lanes 2 to 6) or immunostained for Fn (lanes 7, 8). Lane 1 shows the corresponding amido black staining for proteins. When exposed to either pFn (lane 2) or cFn (lane 3), immunostaining with monoclonal Fn antibodies revealed a reaction with a distinct M_r 190,000 polypeptide, and immunostaining with polyclonal Fn antibodies revealed a similar polypeptide (lane 4, pFn). No reaction was obtained when the RGDS peptide was incubated together with Fns (lane 5, pFn) or was applied on sheets pre-exposed to Fns (lane 6, pFn). Control immunostaining experiments revealed that neither the monoclonal (lane 7) nor the polyclonal (lane 8) Fn antibodies reacted with any polypeptides of K562 cells. Molecular weights of the control proteins are indicated on the left.

Fig 5. Autoradiogram of SDS-PAGE-separated polypeptides of the surface-labeled control (lane 1) and trypsinized K562 cells (lane 2). Note the M_r 190,000/185,000, 120,000, 80,000/70,000, and 50,000 polypeptides of which only the M_r 190,000 polypeptide appeared to be sensitive to trypsin. Molecular weights of the control proteins are indicated on the left.

ments, the binding of Fns to K562 cell polypeptides was totally inhibited (Fig 4, lane 5, pFn), and when the peptide was used to elute the bound Fns, a significant reduction in the binding was observed (Fig 4, lane 6, pFn). Control experiments with both the monoclonal (Fig 4, lane 7) and polyclonal (Fig 4, lane 8) Fn antibodies did not reveal any reaction with the K562 cells.

Surface labeling experiments with the neuraminidase-galactose oxidase-sodium borohydride method revealed that there are a few major surface-exposed glycoproteins in K562 cells, with M_r 190,000, 185,000, 120,000, 80,000 to 70,000, and 50,000 (Fig 5, lane 1). Trypsinization of the cells selectively abolished the M_r 190,000 polypeptide (Fig 5, lane 2). Octylglucoside extraction appeared to remove, apparently quantitatively, all the high M_r polypeptides from surface-labeled K562 cells (Fig 6, lanes 1 to 3). Affinity binding experiments revealed that from the octylglucoside extracts, the M_r 190,000/185,000 polypeptides specifically bound to the GRGDSPC-thiol-Sepharose (Fig 6, lane 4), and their binding could be inhibited when the RGDS peptide was included in the reaction mixture (Fig 6, lane 5).

DISCUSSION

In a series of studies¹⁰⁻¹² Lodish and his coworkers have suggested that murine erythroid cell precursors and erythroleukemia (MEL) cells specifically adhere to Fn and that this process would also play a role in normal erythropoiesis.

In this study K562 human erythroleukemia cells, which have many characteristics of early erythroid precursor cells,¹³⁻¹⁵ also displayed a specific adhesion capacity to Fn

Fig 6. Autoradiogram of SDS-PAGE-separated polypeptides of surface-labeled K562 cells (lane 1), octylglucoside extract of the surface-labeled cells (lane 3), and surface polypeptides remaining in the detergent extracted cells (lane 2). Note that all the high M_r polypeptides appeared to be solubilized in octylglucoside (compare lane 3 to lanes 1 and 2). The 190,000/185,000 doublet of polypeptides bound specifically to the GRGDSPC-thiol-Sepharose (lane 4), and the binding could be inhibited by including the RGDS synthetic peptide in the reaction mixture (lane 5). Molecular weights of the control proteins are indicated on the left.

but not to, eg, laminin. The adhesion process could also be quantitatively inhibited by the tetrapeptide RGDS, like that of many other cells.²⁶⁻²⁸ However, unlike in fibroblastoid cells,² the Fn-binding property of the K562 cells appeared to be trypsin-sensitive. Furthermore, in direct overlay assays a distinct M_r 190,000 binding protein could be revealed in these cells and such a polypeptide selectively bound also to GRGDSPC-Sepharose from octylglucoside extracts of surface-labeled K562 cells.

These results appear to differ from those recently reported on MEL cells,¹¹ which express a major M_r 140,000 Fn-binding protein. This may reflect differences between human and murine erythroleukemia cells, which is evident also in their response to various differentiation-inducing agents.³² Furthermore, multiple interactions between external Fn and cell membrane elements have been recently proposed also in fibroblasts.³³⁻³⁶ Affinity binding experiments with the same Sepharose-coupled synthetic heptapeptide as used in our experiments suggested to Pierschbacher and Ruoslahti²⁸ that the peptide has too low an affinity for the Fn-receptor of fibroblasts and cannot be therefore used in its isolation. Our experiments on fibroblasts showed the same (unpublished), and thus further suggest that both the Fn-binding proteins as well as their affinities for Fns may differ in different cells, although they appear to recognize the same RGD-sequence in Fns.³⁷ Interestingly, our affinity binding experiments revealed a doublet of M_r 190,000 and M_r 185,000 polypeptides, whereas the overlay assays with ¹²⁵I-Fn and with unlabeled Fns only showed a single M_r 190,000 Fn-binding polypeptide. As only the M_r 190,000 polypeptide appeared to be trypsin-sensitive, it may be that in K562 cells the Fn-receptor is a complex of two polypeptides of which only M_r

190,000 polypeptide is capable of recognition of intact Fn. However, when comparing the apparent relative mobilities of putative Fn-receptor proteins from various sources, the recent results of Tamkun et al.³⁸ bear importance: they found that cDNA for the M_r 140,000 fibroblast Fn-receptor codes for an M_r 89,000 polypeptide. Therefore, even major variations in molecular weights may be explained by differences in, eg, glycosylation. For the M_r 190,000 Fn-binding polypeptide of the K562 cells, this remains to be elucidated.

The present results also indicate that human erythroleukemia cells are heterogenous in their response to external Fn, which may be related to different states of differentiation of the cells.³² Thus, while a portion of the K562 cells displayed a spreading capacity to Fn, many of the cells failed to do that.

Many earlier studies have suggested that in fibroblastoid cells there would be some kind of association of the pericellular Fn and the cytoplasmic actomyosin system.³⁹ In fibroblastoid cells, Fn appears to specifically induce fibrillar actin organization in some culture conditions.^{23,36,40} In the K562 cells the spreading process appeared to involve also an

emergence of the actin-microfilaments, which led even to the formation of stress fibers and vinculin-containing adhesion plaques in some of the cells. This suggests that in K562 cells, there are all the actin-associated proteins involved in the formation of stress fibers.⁴¹

The present results show that K562 erythroleukemia cells display an ability to adhere and spread on Fn and that the process is apparently mediated by a distinct receptor-protein and leads to a reorganization of the actomyosin system. The receptor protein appears to be lost in more differentiated cells, suggesting a transient nature for the adhesion process. Further studies are, however, needed to elucidate whether such a receptor-mediated adhesion of human erythroid cells on Fn would participate also in vivo in the regulation of normal or pathologic erythropoiesis.

Monoclonal Antibody 1F5 (Anti-CD20) Serotherapy of Human B Cell Lymphomas

By Oliver W. Press, Frederick Appelbaum, Jeffrey A. Ledbetter, Paul J. Martin, Joyce Zarling, Pamela Kidd, and E. Donnell Thomas

Four patients with refractory malignant B cell lymphomas were treated with continuous intravenous (IV) infusions of murine monoclonal antibody (MoAb) 1F5 (anti-CD20) over five to ten days. Dose-dependent levels of free serum 1F5 were detected in all patients. Two patients had circulating tumor cells and in both cases 90% of malignant cells were eliminated from the blood stream within four hours of initiation of serotherapy. Antigenic modulation did not occur, and sustained reduction of circulating tumor cells was observed throughout the duration of the infusions. Serial bone marrow aspirations and lymph node biopsies were examined by immunoperoxidase and immunofluorescence techniques to ascertain MoAb penetration into extravascular sites. High doses (100 to 800 mg/m²/d and high serum 1F5 levels (13 to 190 µg/mL) were required to

coat tumor cells in these compartments in contrast to the low doses that were adequate for depletion of circulating cells. Clinical response appeared to correlate with dose of MoAb administered with progressive disease (52 mg), stable disease (104 mg), minor response (1,032 mg), and partial response (2,380 mg) observed in consecutive patients. The patient treated with the highest 1F5 dose achieved a 90% reduction in evaluable lymph node disease, but the duration of this remission was brief (six weeks). This study demonstrates that high doses of 1F5 can be administered to patients with negligible toxicity by continuous infusion and that clinical responses can be obtained in patients given >1 g of unmodified antibody over a ten-day period.

MONOCLONAL ANTIBODY (MoAb) serotherapy of malignancy represents a theoretically attractive, potentially nontoxic approach for the treatment of neoplastic disease.¹⁻³ Preliminary animal experimentation has demonstrated both the effectiveness and limitations of MoAbs that recognize tumor-associated antigens in preventing growth of murine hematologic malignancies.^{4,5} Early human trials have shown that infusion of antibodies recognizing lymphoid cell differentiation antigens is a well-tolerated therapy capable of coating tumor cells and causing tumor regression in some patients.⁶⁻⁸ However, the antitumor effectiveness of MoAbs has been limited by the presence of circulating free antigen, antigenic modulation, development of human antimouse antibodies (HAMA), emergence of antigen-negative tumor cell variants, and the inadequacy of host effector cell mechanisms.^{5,8-11}

Here we present findings in four patients with B cell lymphomas treated with a murine IgG2a MoAb (1F5) chosen to avoid many of the previously encountered obstacles. MoAb 1F5 recognizes a 35,000 dalton antigen (Bp35,

CD20) present on the surface of normal and malignant B cells¹² that is not shed from the cell surface (unpublished observations), does not modulate in response to MoAb binding, and does not bind to any other normal tissues. Consequently, prolonged continuous MoAb 1F5 therapy can be administered without inducing the unresponsiveness to therapy that has necessitated intermittent bolus therapy in previous trials.⁸⁻¹¹ We have administered 1F5 by continuous intravenous (IV) infusion (52 to 2,380 mg over five to ten days) to determine toxicity, kinetics, penetration to extravascular tissues, and efficacy. Our studies have shown 1F5 to be a minimally toxic therapy capable of depleting circulating tumor cells at low doses and lymph node tumor cells at high doses. However, responses were transient, suggesting that antibodies conjugated to toxins or radioisotopes might afford more lasting clinical benefit than unmodified antibody.

MATERIALS AND METHODS

Antibody preparation. Murine MoAb 1F5 (IgG2a) was produced in BALB/c mice and purified as previously described.¹³ Antibody 1F5, along with the B1 antibody,¹⁵ has been assigned to the CD20 (anti-Bp35) cluster group by the Second International Workshop on Human Leukocyte Differentiation Antigens.¹⁴ The reactivity of antibody 1F5 with normal and malignant B cells has previously been reported.^{13,16,17} MoAb 1F5 was purified from ascites by saturated ammonium sulfate precipitation followed by diethyl aminoethyl (DEAE)-Sephacryl (Pharmacia, Piscataway, NJ) column chromatography.¹⁶ Testing of the purified antibody by Microbiological Associates (Bethesda, MD) has shown it to be free of bacterial, viral, or endotoxin contamination. Preclinical testing in two macaques (*M. fascicularis*) injected with 1F5 IV showed that this antibody was capable of eliminating circulating B cells and penetrating lymph nodes without causing any acute toxicity (J. Ledbetter, unpublished observation, 1983). A battery of normal human autopsy tissues was screened for reactivity with antibody 1F5 by an indirect immunoperoxidase method. No reactivity was seen with any tissue except those known to be rich in B lymphocytes (tonsils, lymph nodes, spleen). Tissues failing to bind 1F5 included heart, thyroid, adrenal, lung, muscle, kidney, testis, skin, colon, breast, and brain.

Patient selection. Adult patients with histologically confirmed B cell lymphomas shown by immunoperoxidase or immunofluorescence techniques to be reactive with the 1F5 antibody were eligible

for this study if they had failed previous conventional therapy (chemotherapy and/or radiotherapy), if they had normal renal and hepatic function (creatinine <2.0 mg/dL, bilirubin <1.5 mg/dL), had evaluable disease, had not received any other treatment for $\geq$ four weeks, had no other active medical problems, and signed an informed consent approved by the Institutional Review Board of the Fred Hutchinson Cancer Research Center.

Study design. Prestudy blood, marrow, and lymph node specimens were obtained and analyzed by conventional histopathology and by an indirect immunoperoxidase method (Vectastain, Vector Laboratories, Raritan, NJ) for evidence of tissue involvement with tumor cells capable of binding 1F5. Cell suspensions of these tissues were analyzed by two-color flow cytometry using a panel of fluorescein and phycoerythrin antibody conjugates¹³ to determine the baseline immunologic phenotypes of the resident cell populations (see below). Intradermal skin testing with 10 μ g of antibody 1F5 in 0.1 mL of normal saline was performed, and no hypersensitivity responses were observed. Allopurinol (300 mg/d) was given throughout antibody administration. A bolus loading dose was given over one to two hours IV to rapidly achieve steady state serum antibody levels. The loading dose was calculated from the following equation: Loading dose = $1.4 \times$ elimination half-time (in days) $\times$ daily maintenance dose.¹⁸ Preclinical studies of murine anti-CD20 antibody infusions in nonhuman primates (Ledbetter, unpublished data) and clinical trials of murine MoAbs administered to patients with graft-v-host disease (GVHD)¹⁹ suggested an elimination half-time of 1.2 days, and this figure was used in calculating the loading doses. Patients were assigned a predetermined maintenance antibody dose that was diluted in 500 mL normal saline and administered by continuous IV infusion for five to ten days. (Patient 1 had premature discontinuation of his infusion after five days due to rapidly progressive lymphoma.) The maintenance antibody doses administered to the patients are summarized in Table 1. The dose escalation range was chosen to progress from safe low doses (5 mg/m²/d) known to be well tolerated for other MoAbs^{6,7,9,10,19} to high doses (400 to 800 mg/m²/d), which we felt were more likely to result in good tissue penetration. We initially planned to escalate doses between patients. However, because of the absence of toxicity, poor penetration of low doses of antibody into patients 1 and 2, and slow patient accrual, doses were escalated progressively in patients 3 and 4 (from 10 mg/m²/d to 800 mg/m²/d) to achieve high circulating antibody levels that we felt would be more likely to achieve extravascular tissue penetration.

Table 1. Summary of Patient Characteristics

Patient	1	2	3	4
Age/Sex	42/M	64/M	63/M	45/M
Type of Lymphoma	DML	WDLL	DPDL	DHL
Stage	IVB	IVA	IVA	IVB
Total Dose of 1F5	52.4 mg	104.8 mg	1,032 mg	2,380 mg
Duration of Therapy	4.5 days	10 days	10 days	7 days
Response	Progression	Stable Disease	Minor Response	Partial Response

Abbreviations: DML, diffuse mixed small and large cell lymphoma; WDLL, diffuse well-differentiated lymphocytic lymphoma (small lymphocytic, working formulation); DPDL, diffuse, poorly differentiated lymphocytic lymphoma (diffuse small cleaved cell, working formulation); DHL, diffuse "histiocytic" lymphoma (diffuse large cell lymphoma, working formulation).

Patient monitoring. Pretreatment tests included a history and physical examination, relevant radiographic studies and computed tomographic scans, chemistry batteries, uric acid levels, complete blood cell counts (CBCs) and differentials, prothrombin time, partial thromboplastin time, serum complement levels (CH50, C4, C3), immune complex levels (C1Q binding assay), urinalysis, ECG, and cell surface marker analysis. Patients were examined twice daily during antibody infusion. Serial serum specimens for 1F5 levels and antimouse antibody levels, blood counts, chemistries, and blood specimens for surface marker studies were obtained four hours after initiation of 1F5 therapy and daily thereafter. Patients were discharged at the termination of antibody infusions. Blood samples were obtained on an outpatient basis for the above tests on days 1, 2, 7, and 21 after cessation of therapy and monthly thereafter. Serum complement and immunoglobulin levels were tested pretreatment and on days 1, 5, and 10 and then at roughly monthly intervals for six months.

Response criteria. Standard response criteria were employed as follows: Complete response-disappearance of all measurable and evaluable disease; Partial response: reduction by $\geq 50\%$ of leukemic cell counts and $\geq 50\%$ reduction in the size of a measurable lesion, and no increase in the size of any measurable or evaluable lesions or appearance of new lesions; Stable disease: Less than a partial response without an increase of $>25\%$ in leukemic cell count and $<25\%$ increase in any measurable lesion. Progression: Increase in leukemic cell count ($>25\%$), appearance of new lesions, or an increase of 25% or greater in any measurable lesion.

Measurement of free 1F5 and human antimouse antibody. Serum 1F5 levels and human antimouse antibody levels (HAMA) were measured by solid phase competitive inhibition radioimmunoassay (RIA) as previously described.¹⁹

Detection of cell-bound 1F5. Assessment of tumor cell coating by infused antibody 1F5 was accomplished on serial specimens of peripheral blood, bone marrow, and lymph nodes by indirect immunoperoxidase and immunofluorescence techniques. Peripheral blood and bone marrow mononuclear cells were obtained by Ficoll-Hypaque (LSM, Litton Bionetics, Kensington, MD) density gradient centrifugation. Lymph node biopsies were divided in thirds: one portion was minced into a single cell suspension, another part was fixed in formalin for routine histologic staining, and another portion was frozen in liquid nitrogen for immunohistologic staining. Lymph node frozen sections were fixed to gelatin-coated glass slides and stained with rabbit antimouse immunoglobulin (Vectastain, Vector Laboratories, Raritan, NJ) using an indirect avidin-biotin technique. Pretreatment biopsies served as controls.

Cell suspensions of blood, bone marrow, and lymph nodes from antibody-treated patients were examined by flow cytometry (FACS IV, Becton Dickinson, Sunnyvale, CA) for the presence of surface 1F5 by using fluorescein-conjugated goat antimouse immunoglobulin (FITC-GAM1g; TAGO, Burlingame, CA). The mean fluorescence intensity of cells stained with FITC-GAM1g was compared to the intensity of cells incubated with excess 1F5 in vitro before staining to assess the saturation of binding sites in vivo. Relative CD20 surface antigen density was estimated for normal and malignant B cells by measuring the mean fluorescence intensity of cells stained in vitro with saturating quantities of fluorescein-conjugated anti-CD20 antibody after correcting for nonspecific fluorescence with a control reagent.^{13,17}

Tumor cell surface antigen phenotypes were determined by both immunofluorescence and immunoperoxidase methods using peroxidase, fluorescein, or phycoerythrin conjugates of MoAbs 10.2 (anti-CD5), HB10a (anti-DR), G1-4 or 3E10 (antikappa), and 2C3 (anti- μ) as previously described.^{13,17} Serial monitoring of these tumor cell markers demonstrated that CD20-negative tumor cells were not

generated during 1F5 therapy by antigenic modulation (data not shown).

CASE HISTORIES

Patient 1 was a 42-year-old man with stage IVB diffuse, mixed, small and large cell lymphoma who presented in 1982 with fever, diffuse lymphadenopathy, and hepatosplenomegaly. Previous therapy included CHOP (cyclophosphamide, adriamycin, vincristine, and prednisone) chemotherapy, intrathecal methotrexate, whole brain irradiation, splenectomy, sequential upper and lower hemibody irradiation, and four cycles of bleomycin, cytosine arabinoside, vincristine, procarbazine, and prednisone. He was referred for 1F5 therapy in July, 1984 because of refractory disease. He did not respond to low-dose 1F5 and was taken off study after five days of infusion because of progressive bone marrow (BM) and liver replacement with tumor. Salvage CHOP chemotherapy was given, but the patient died of progressive lymphoma on March 16, 1985.

Patient 2 is a 64-year-old man with stage IVA diffuse, small, lymphocytic lymphoma diagnosed by lymph node (LN) and BM biopsy in 1976. He received multiple chemotherapeutic regimens (CVP, CHOP, chlorambucil, and CCNU, etoposide, and methotrexate) with partial responses. He was referred for 1F5 serotherapy in December 1984, 11 months after his last course of chemotherapy. He did not respond to low dose 1F5 but had stable disease that did not require therapy until the summer of 1985 when he was begun on bleomycin, etoposide, BCNU, and Decadron, to which he remains partially responsive.

Patient 3 was a 63-year-old man with stage IVA diffuse, small, cleaved-cell lymphoma involving lymph nodes, marrow, and spleen. Previous therapy included splenectomy, chlorambucil, and CVP. He was referred for 1F5 therapy in December 1984, one month after his last cycle of CVP because of the development of refractory disease with rapidly progressive adenopathy and lymphocytosis ($>30,000$ cells/ μ L). He showed a minor response to intermediate dose 1F5 therapy. ProMACE/MOPP chemotherapy was given in January and February 1985 without response. A partial response occurred after therapy with high-dose cytosine arabinoside, but the patient died with marrow aplasia in July 1985.

Patient 4 was a 45-year-old man with sclerosing, diffuse large-cell lymphoma presenting in January 1983 with bowel and lymph node involvement. Therapy included eight cycles of CHOP, intrathecal methotrexate, involved field abdominal radiation, prophylactic cranial irradiation, and allogeneic marrow transplantation (in March 1984). He was referred for 1F5 therapy because of refractory lymphoma in late October 1985. He had been on dexamethasone (4 mg/d) for many months as symptomatic therapy for myalgias, and this was continued during serotherapy. After treatment with 1F5 there was a partial response that lasted six weeks. He then redeveloped progressive lymphoma and refused further treatment. He expired on December 21, 1985.

RESULTS

Serum 1F5 levels. Circulating free antibody levels were detectable by RIA in all patients throughout the period of infusion (Fig 1). Patients 1 and 2 received MoAb doses of 5 mg/ m^2 /d and consistently had 1F5 serum concentrations of 0.3 to 1.0 μ g/mL. Patients 3 and 4 received escalating antibody doses and had corresponding increases in 1F5 levels. For comparable antibody doses the patients with circulating antigen-positive tumor cells (1 and 3) had lower serum levels of 1F5 than the patients who did not have significant numbers of circulating malignant lymphocytes (2 and 4, see Fig 1), probably reflecting the effect of antibody

Fig 1. Serum 1F5 concentrations in patients receiving continuous infusions of antibody. MoAb 1F5 concentrations were determined by solid phase radioimmunoassay. The doses of 1F5 infused in each patient are indicated by the superimposed stippled bars. (A), patient 1; (B), patient 2; (C), patient 3; (D), patient 4.

binding to tumor cells. Antibody remained detectable in the serum for as long as three weeks after termination of infusion in patient 4 (peak concentration 190 μ g/mL). However, 1F5 levels fell into the undetectable range within three days of termination of infusion in patients 1 and 2 (peak levels 1 μ g/mL) and within two weeks in patient 3 (peak level 13.4 μ g/mL). Rough estimates of the serum elimination half-times were calculated to be 24 hours for patient 1 (from 0.93 μ g/mL to .22 μ g/mL in the 48 hours after termination of infusion), 42 hours for patient 3 (from 13.4 μ g/mL to 9.0 μ g/mL in 24 hours), and 52 hours in patient 4 (from 179 to 35.6 μ g/mL over five days). Data for patient 2 were insufficient for estimation of a serum half-life. These elimination half-times are in good agreement with previous studies of murine anti-CD20 antibodies in nonhuman primates (J. Ledbetter, unpublished results) and studies of murine anti-T cell antibodies in patients with GVHD.¹⁹

CD20 antigen density on tumor cells. Table 2 summarizes the relative Bp35 surface antigen densities on patient lymphoid cells from blood, bone marrow, and lymph nodes as determined by direct immunofluorescent analysis.^{13,17} The density of this antigen on normal B lymphocyte populations is also listed for comparison. Patients 1 and 4 had CD20 densities on their malignant cells comparable to those seen on normal, resting B lymphocytes (eg, peripheral blood B cells and tonsil mantle zone B cells¹³). Patient 3 had a much higher surface antigen density on his lymphoma cells, comparable to that observed on normal, activated B cells (tonsil germinal center cells¹³). Patient 2 had a very low Bp35 antigen density on his lymph node and bone marrow tumor cells with a mean fluorescence intensity only 3.5 times higher than control cell populations lacking the antigen. (This degree of staining was unequivocally greater than control, however.) Patients 2 and 4 had negligible numbers of circulating tumor cells morphologically, confirming the negligible staining with FITC-1F5 seen by immunofluorescence (nearly all circulating lymphocytes were T cells in these patients). Of interest, the bone marrow of patient 4 was grossly involved with tumor but failed to bind FITC-1F5, suggesting that an antigen-negative tumor cell variant was responsible for infiltration of this tissue. With this single exception, the different sites of lymphomatous involvement within a given patient showed similar CD20 antigen densi-

*Expressed as the linear channel number of the mean fluorescence intensity measured on a FACS IV cell sorter for cells stained with saturating concentrations of fluorescein-conjugated anti-CD20 antibody by the method of Ledbetter and Clark.¹³

†Negative control (unstained) cells also showed a mean fluorescence intensity of 2.

‡Patient 1 had an unascrable marrow and no accessible adenopathy, so immunofluorescent studies were done solely on circulating malignant cells.

ties. No definitive conclusion regarding the clinical responsiveness of tumors bearing different surface CD20 densities is possible because of the small number of patients treated and variable antibody doses administered.

Effects of 1F5 on peripheral blood lymphocytes. Two patients (1 and 3) had appreciable numbers of circulating malignant cells. In both patients antibody administration resulted in an immediate decrease in the number of circulating tumor cells (assessed by morphological criteria and by surface immunologic phenotypes). Patient 1 had an 86% decline in the number of blood lymphoma cells (from $1.27 \times 10^3/\mu\text{L}$ to $0.18 \times 10^3/\mu\text{L}$) within four hours of institution of 1F5 therapy. Patient 3 had a 91% decrement in circulating tumor cells (from $18.21 \times 10^3/\mu\text{L}$ to $1.61 \times 10^3/\mu\text{L}$) in the same brief time interval (Fig 2). These effects were obtained with low doses of antibody in both patients ($5 \text{ mg}/\text{m}^2$ and $10 \text{ mg}/\text{m}^2$, respectively) and were sustained throughout the entire period of infusion (five and ten days). Flow cytometry of circulating PBL stained with FITC-GAM1g demonstrated saturation of 1F5 antibody binding sites on tumor cells in both patients (although complete saturation in patient 3 was only achieved at the higher dose of $100 \text{ mg}/\text{m}^2/\text{d}$, Fig 3). Serial tumor cell surface-antigen phenotyping (using two-color immunofluorescence with reagents recognizing other tumor-associated antigens [see Materials and Methods]) demonstrated that antigenic modulation did not occur (data not shown). In both patients termination of 1F5 therapy was accompanied by a rapid reappearance of

**Fig 2. Depletion of circulating lymphoma cells in patient 3 during infusion of MoAb 1F5.**

circulating tumor cells that reached pretreatment levels within two to three days (Fig 2).

Effects of 1F5 on bone marrow tumor cells. Patients 1, 2, and 3 had evaluable marrow involvement with lymphoma. In patients 1 and 2, antibody doses of $5 \text{ mg}/\text{m}^2/\text{d}$ were not sufficient for saturation of 1F5 antibody binding sites on tumor cells in the marrow. Patient 3 received escalating doses of 1F5 in conjunction with serial marrow aspirations to estimate the amount of antibody required for coating of tumor cells in the marrow. Serial fluorescence histograms (Fig 4) clearly showed that an antibody dose of $10 \text{ mg}/\text{m}^2/\text{d}$ was insufficient (4% saturation of Bp35 binding sites) but that $100 \text{ mg}/\text{m}^2/\text{d}$ could produce significant coating (61% saturation of Bp35 binding sites) of marrow tumor cells.

**Fig 3. In vivo labeling of circulating tumor cells with 1F5 antibody in patient 3 as assessed by serial flow cytometry of peripheral blood lymphocytes with FITC-GAM1g (to detect mouse antibody 1F5 bound to tumor cells in vivo) and FITC-1F5 (to detect unoccupied Bp35 [CD20] binding sites). Pretreatment PBL stained brightly with FITC-1F5 because of abundant free CD20 sites on circulating lymphoma cells. Serial histograms on days 2, 5, and 10 revealed coating of PBL with 1F5 (detected with FITC-GAM1g). Saturation of binding sites is shown on day 10 by absence of unoccupied Bp35 receptors capable of binding FITC-1F5. By two weeks posttreatment, bound murine MoAb was no longer detectable on PBL.**

Fig 4. Penetration of MoAb 1F5 into bone marrow of patient 3 during serotherapy as assessed by flow cytometry of mononuclear cells from BM aspirates using FITC-GAMlg (to detect cell-bound 1F5) and FITC-1F5 (to detect unbound Bp35 sites).

Regression of marrow lymphoma was not seen in any of these three patients.

The marrow of patient 4 was unusual in that it appeared to contain tumor cells that did not express the Bp 35 antigen. Although marrow aspirates and biopsies contained unequivocal large cell lymphoma, no tumor cells reactive with FITC-1F5 were detected by flow cytometry. In contrast, tumor cells in cervical and inguinal lymph nodes had the same morphology as the cells in the marrow but reacted strongly with antibody 1F5 as assessed by both immunoperoxidase and immunofluorescence techniques (see Table 2). As would be anticipated, infusion of antibody 1F5 had no effect on the antigen-negative tumor cells in the marrow of this patient.

Effects of 1F5 on lymph nodes. Patients 2, 3, and 4 had evaluable adenopathy that was biopsied before treatment and on the last day of antibody infusion. Immunoperoxidase and immunofluorescent analyses showed no penetration of antibody 1F5 into the nodes of patient 2 (who received 105 mg over ten days). There was minor perivascular penetration detectable only by immunoperoxidase methods in patient 3 (1,032 mg over ten days). In contrast, significant coating of tumor cells detectable by both immunoperoxidase and immunofluorescence (Figs 5 and 6) was present in patient 4 (2,380 mg over seven days) with 69% saturation of available binding sites. In vitro studies showed that an ambient 1F5 antibody concentration of 24 μ g/mL was necessary to achieve 69% saturation of cell-surface binding sites. Since the serum 1F5 concentration in patient 4 at the time of his lymph node biopsy was approximately 190 μ g/mL, we estimate that a 1F5 antibody gradient of 8:1 existed between serum and lymph node interstitial fluid.

No clinical response was observed in the nodes of patient 2. Some inguinal nodes regressed by 25% in patient 3, but most lymph nodes were unaffected. There was marked regression of all nodes in patient 4 with a calculated >90% reduction in tumor burden (Fig 7). Of note, the diminution of LN size did not begin until day 5 of antibody infusion, and progressive node shrinkage continued for three weeks after cessation of 1F5 infusion. The response duration was brief, however, with regrowth of LN occurring six weeks after therapy.

Overall clinical response. Patient 1 had diminution of

Fig 5. Indirect immunoperoxidase staining of lymph node frozen sections with GAMlg to detect *in vivo* labeling of tumor cells during murine MoAb 1F5 serotherapy (original magnification $\times 250$). (A) Patient 2: LN biopsy performed on day 10 of therapy while receiving 5 mg/m²/d of antibody 1F5. Negligible staining indicates absence of penetration of LN by antibody at this dose. (B) Patient 3: LN biopsy performed on day 9 of therapy while receiving 100 mg/m²/d of 1F5. Staining of tumor cells in perivascular locations is present. (C) Patient 4: LN biopsy performed on day 10 of therapy while receiving 800 mg/m²/d of 1F5. Peroxidase staining is appreciable at this dose, although the distribution remains heterogeneous. (D) Saturation of 1F5 binding sites in patient 3 by *in vitro* incubation of an LN section with excess 1F5 antibody. The section shown in this figure was from the same LN biopsy depicted in Fig 4B.

Fig 6. Analysis of 1F5 penetration into LN during serotherapy assessed by flow cytometry of LN suspensions. FITC-GAM1g was used to detect *in vivo* coating of tumor cells with antibody 1F5. Patient 2 had only a small subpopulation of LN cells possessing the Bp35 antigen (shown with FITC-1F5). No penetration of 1F5 into LN could be shown with FITC-GAM1g. Virtually all LN cells in patient 3 possessed the Bp35 antigen and stained intensely with FITC-1F5, but poor *in vivo* penetration of 1F5 had occurred as shown by absence of FITC-GAM1g staining. (Immunoperoxidase staining of LN sections was capable of demonstrating some penetration of 1F5 into this LN, however [see Fig 5B]). Patient 4 had significant penetration of 1F5 into LN as shown by staining with FITC-GAM1g.

circulating tumor cells, but progressive liver and marrow lymphoma required premature termination of 1F5 therapy and institution of salvage chemotherapy. Patient 2 had no response of his evaluable marrow or LN disease. Patient 3 had a minor response consisting of transient 90% reduction of circulating tumor cells and 25% shrinkage of some but not all LN but no response in the marrow. Patient 4 had a partial response consisting of 90% reduction of all evaluable LN.

Toxicity. No clinically significant toxicity was observed in any of our patients. Patients 1 and 4 had asymptomatic, intermittent, low-grade fever (38 to 39 °C) lasting six days and two hours, respectively. Transient decrements of platelet and neutrophil counts to 50% to 75% of baseline levels were observed in all four patients. These changes were rapidly reversible in all cases except patient 1, where progressive cytopenias were clearly due to marrow replacement with tumor. In the other three instances, the blood counts stabilized after one to two days and often demonstrated some recovery, even before discontinuation of antibody infusion. No bleeding or infectious episodes occurred during antibody treatment. No allergic, pulmonary, renal, hepatic, or cutaneous sequelae occurred. Renal function as measured by 24-hour creatinine clearance was unchanged after completion of antibody therapy. Complement consumption was observed in patients 1 (40% reduction of CH₅₀ and C4 levels) and 3 (97% reduction of CH₅₀, 94% reduction of C4 levels), but circulating immune complexes could not be detected at any time in any patient.

Fig 7. Reduction in tumor burden in patient 4. A 90% reduction in LN volume was observed over a four-week period.

Effects of 1F5 on normal B cells. Attempts to monitor numerical changes and functional alterations of normal B cells in patients receiving 1F5 serotherapy (by assessing proliferative responses to polyclonal B cell mitogens and *in vitro* Epstein-Barr virus (EBV)-induced immunoglobulin synthesis) were precluded by the extremely low numbers of normal B cells that could be harvested from these patients following antibody infusion. The paucity of B cells was due to two factors: baseline deficiency of normal B lymphocytes (a common feature of advanced, refractory B cell malignancies) and depletion of normal as well as malignant B cells by 1F5 therapy (which has also been documented in normal nonhuman primates infused with anti-CD20 antibodies, [Jeffrey Ledbetter, unpublished results]). Quantitative immunoglobulin levels were carefully monitored in all patients before, during, and for up to five months after 1F5 therapy. Baseline hypogammaglobulinemia was present in patients 1 and 3, but no patient demonstrated a decline in any subclass of immunoglobulin consequent to 1F5 therapy.

Human antimouse antibody levels. IgM HAMA were undetectable by RIA in all patients. Low levels of IgG HAMA (2 × pretreatment control levels) became detectable five months after serotherapy in patient 1 only.

DISCUSSION

This report summarizes our findings in four patients with refractory malignant B cell lymphomas treated with MoAb 1F5 (anti-CD20) by continuous IV infusion for five to ten days. Our study differs from previous serotherapy trials of hematologic malignancies by employing an antibody directed against a nonmodulating antigen. This feature allowed us to maintain continuous high serum antibody levels without inducing the tumor refractoriness generally encountered with modulating antigens.^{8-11,20} The continuous infusion mode of administration allowed delivery of very high doses of antibody (up to 800 mg/m²/d in patient 4) without the significant pulmonary toxicity that is often observed following bolus injection of high MoAb doses.^{8,10,21} Serial kinetic measurements revealed a dose-dependent relationship between the amount of antibody infused and the concentration of free MoAb in the blood stream. We found that even low doses of 1F5 (5 to 10 mg/m²/d) were capable of depleting circulating tumor cells from the blood stream analogous to observations made using murine MoAbs T101 (for chronic lymphocytic leukemia) and J5 (for acute lymphocytic leukemia).^{9-11,20} However, in contrast to the studies with modulating antibodies T101 and J5 given by prolonged or repeated administration, the responses induced by the nonmodulating 1F5 were sustained throughout the duration of the infusion (five to ten days).

Although small doses of 1F5 sufficed to deplete circulating tumor cells, penetration of antibody into extravascular sites such as bone marrow and lymph nodes proved to be much more problematic. Intravenous administration of 400 to 800 mg/m²/d was required to achieve 69% saturation of binding sites on lymph node tumor cells. Even at these doses the intranodal distribution of antibody was heterogeneous. The immunoperoxidase staining patterns observed in LNs

suggested passive diffusion of antibody down a concentration gradient from small blood vessels into the LN parenchyma. The clinical responsiveness observed appeared to correlate with 1F5 dose administered, peak-serum MoAb concentration achieved, and degree of extravascular tissue penetration obtained. A total dose of 52.4 mg was associated with progressive disease (patient 1), 104.8 mg resulted in stable disease in patient 2, 1,032 mg caused a minor response in patient 3, and 2,380 mg produced a partial response in patient 4.

These observations have been made on a very small group of patients, each of whom had a different type of B cell lymphoma. The degree to which our findings might be applicable to other lymphoma patients is unclear, since each patient has a different tumor burden and distribution, different numbers of circulating malignant cells acting to absorb infused MoAb, and different surface densities of the Bp35 antigen. Consequently, the dose levels and kinetic data found in our patients can only serve as a rough guideline for the management of other patients with this antibody. Generalizations from our findings with 1F5 to other MoAbs should be made with caution in light of recent studies demonstrating dramatic, unpredictable kinetic and functional differences among different antibodies recognizing the same antigen.²²

The toxicity seen in these four patients was insignificant. Minor fever and moderate cytopenias were the only adverse effects observed despite administration of massive doses of antibody 1F5 to patients 3 and 4. Since neither platelets nor neutrophils express the Bp35 antigen or label with FITC-1F5, the exact mechanism for the decrement in neutrophil and platelet counts is uncertain. It is of interest that similar decrements in blood counts have also been observed in patients treated with anti-idiotypic antibodies.⁸ Small quantities of antibody might be absorbed via Fc receptors to these cells, which may then be removed from the circulation by the reticuloendothelial system. Although the development of HAMA has been a major problem in some reported series,^{8,23} antimouse antibodies were detected in only one of our four patients, and in this patient they did not appear until five months after 1F5 therapy was completed. These findings are in accord with other studies demonstrating that patients with B cell malignancies undergoing monoclonal serotherapy seldom develop HAMA, whereas patients with T cell malignancies or solid tumors receiving similar treatment often develop antimouse antibodies.^{24,25}

Previous trials of MoAb serotherapy have also generally encountered minimal toxicity.³ The major adverse events described to date involved anaphylactoid reactions in patients with large circulating tumor cell burdens and/or high circulating antigen levels given high doses of antibody by rapid bolus injection.^{8,10,21} These episodes have been ascribed to pulmonary leukostasis resulting from sequestration of antibody-coated tumor cells in the pulmonary vasculature leading to wheezing, dyspnea, and hypotension. The absence of circulating antigen and the prolonged duration of antibody administration in our trial were mitigating factors that probably helped avoid these untoward sequelae in our patients.

The relative merits of continuous infusion of MoAbs

compared with intermittent bolus therapy remain debatable. For many antibodies continuous infusion is not feasible because of antigenic modulation. In such circumstances intermittent therapy is necessary to allow regeneration of cell surface antigen. The bolus method is less cumbersome than continuous infusion and achieves higher peak MoAb concentrations for equivalent doses. Whether the maintenance of uniform high-circulating antibody levels and reduction in toxicity achievable with continuous infusion are sufficiently advantageous to offset the inconveniences remains unanswered. Nevertheless, maintenance of steady state antibody levels in this trial has afforded an advantageous setting for kinetic measurements and for the assessment of the serum concentrations required for MoAb penetration into the extravascular space.

The mechanisms by which unmodified MoAbs might cause elimination of tumor cells *in vivo* remain controversial. Most workers currently view antibody-dependent cellular cytotoxicity and reticuloendothelial system phagocytosis of MoAb-coated cells as the most likely processes involved.^{3,26} Murine MoAbs (including 1F5) fix human complement poorly *in vitro*, and consequently complement-mediated tumor cell lysis is not thought to be of major significance *in vivo*. The significant consumption of complement in two of our four patients was unexpected and suggests a possible role for complement in eliminating tumor cells.

The short, incomplete responses obtained with serotherapy using unmodified MoAbs have been of minimal clinical benefit (with the notable exception of the patient described by Miller et al).⁷ Consequently, innovative MoAb administration schedules, testing of new antibodies, and administration of antibody conjugates will be necessary if the promise of monoclonal serotherapy is to be realized. Badger et al have already convincingly demonstrated cures of lymphomas in mice treated with radioiodinated MoAbs in a setting in which unmodified MoAbs were ineffective.²⁷ Recent clinical reports of responses in patients with Hodgkin's disease or hepatoma treated with radioiodinated antiferritin antibodies suggest that this approach will also be useful in man.^{28,29} Radiolabeled MoAbs can potentially kill not only the tumor cells to which they bind but could also kill neighboring cells that do not bind antibody by virtue of poor tissue penetration, antigenic modulation, or somatic mutation ("antigen-negative variants"). Toxin-antibody conjugates are similarly promising,³⁰ although antigens such as CD20, which are not endocytosed after ligand binding,³¹ might not be good targets for this approach, since immunotoxin internalization is generally required for cell killing.³² The findings of our current pilot study should assist in the rational design of subsequent trials employing such radiolabeled or toxin-conjugated immunotoxins.

ACKNOWLEDGMENT

We thank Mary Gallagher, Marsha Bolton, and Terri McLaren for competent assistance in performance of the immunofluorescence and immunoperoxidase studies and Anajane Smith for help in performance of the radioimmunoassays. We are grateful to Drs H. Straley, A. Keller, and S. Speckart for referring patients for these trials.

Comparative Thrombolytic Properties of Single-Chain Forms of Urokinase-Type Plasminogen Activator

By David C. Stump, Jean M. Stassen, Eddy Demarsin, and Désiré Collen

The specific thrombolytic properties of urokinase and three molecular forms of single-chain urokinase-type plasminogen activator (scu-PA) were compared in a human plasma milieu *in vitro* and in an experimental thrombosis model in rabbits. These scu-PA molecules included M_r 54,000 scu-PA from human urine (urinary scu-PA), scu-PA from conditioned media of a human lung adenocarcinoma cell line (CALU-3, ATCC, HTB-55) (cellular scu-PA) and an M_r 32,000 proteolytic derivative of cellular scu-PA (scu-PA-32k). All four molecular forms induced significant lysis of a ^{125}I -labeled human plasma clot immersed in citrated human plasma at concentrations between 50 and 200 IU/mL. None of the four showed absolute fibrin-specificity, but at equivalent lytic dose the three single-chain forms appeared to cause less fibrinogen degradation and α_2 -antiplasmin consumption than two-chain urokinase. In addition, the fibrinolytic potential of the three single-chain forms was largely maintained during pre-incubation in plasma for up to 48 hours whereas that of urokinase was

completely inhibited. Intravenous (IV) infusion of cellular scu-PA or scu-PA-32k into rabbits with a ^{125}I -labeled thrombus in the jugular vein caused significant dose-dependent lysis at concentrations ranging from 8,700 to 35,000 and from 9,000 to 36,000 IU/kg respectively. Clot lysis was accompanied by minor α_2 -antiplasmin consumption or fibrinogen breakdown. In contrast, urokinase induced lysis at doses between 20,000 and 200,000 IU/kg, but at higher doses was associated with significant systemic activation of the fibrinolytic system. It is concluded that scu-PA obtained from CALU-3 cell cultures has identical thrombolytic properties to that obtained from urine. In addition, the scu-PA-32k proteolytic derivative has the same fibrin-specific thrombolytic properties as the intact molecule. Cellular scu-PA and scu-PA-32k may therefore constitute more readily available alternatives for clot-selective thrombolytic therapy in man.

CONVERSION of plasminogen to plasmin is the key event occurring during physiologic fibrinolysis. Most efficiently it occurs at or near the fibrin surface where rapid inhibition of the generated plasmin does not take place.¹ Urokinase, obtained from human urine,² activates both circulating and fibrin-bound plasminogen similarly. As a result, it induces fibrinolysis but only in association with the so-called "lytic state," characterized by consumption of α_2 -antiplasmin and fibrinogen breakdown, which may predispose to bleeding.³ In contrast, fibrin-specific thrombolysis is now possible with tissue-type plasminogen activator (t-PA), which efficiently activates plasminogen only in the vicinity of a blood clot⁴ as the result of its specific affinity for fibrin.⁵ Its promise as a fibrin-specific thrombolytic-in-man agent has now been confirmed.⁶

More recently, a single-chain molecular form of urokinase has also been recognized as a potential fibrin-specific thrombolytic agent.⁷⁻¹² These molecular forms of urokinase have been designated pro-urokinase or preferably single-chain urokinase-type plasminogen activator (scu-PA).¹³ According to some studies, scu-PA activates plasminogen with high

affinity ($K_m < 1 \mu\text{mol/L}$), even in the absence of fibrin,^{14,15} but this activity is inhibited by plasma. However, with the presence of fibrin in plasma, scu-PA regains its plasminogen-activating potential, though not via direct binding to fibrin. To date scu-PA has not become widely available for use in biochemical and clinical studies. The most readily available biological source of scu-PA, human urine, indeed contains such small amounts ($< 15 \mu\text{g/L}$)^{16,17} that it is impractical for use in large-scale purification. Moreover, to date, urinary scu-PA, though fully characterized physicochemically and kinetically,¹⁷ has not been shown to be stable in plasma or to have clot-selective fibrinolytic properties in plasma.

A more widely available and enriched secondary source (CALU-3 cells) of scu-PA has been identified and a straightforward method for its purification developed.¹⁸ This has also led to the identification of a novel proteolytically modified M_r 32,000 form of scu-PA,¹⁹ which has similar kinetic properties as intact scu-PA. The purpose of the present study was to compare the thrombolytic properties of urinary scu-PA, cellular scu-PA, and scu-PA-32k with those of urokinase.

MATERIALS AND METHODS

Human urinary scu-PA was purified as described¹⁷ with a specific activity of 51,000 IU/mg as determined by calibration against the International Reference Preparation for Urokinase (66/96) obtained from Dr P.J. Gaffney, National Institute for Biological Standards and Control, London, UK. Cellular scu-PA was purified from conditioned media of cultured human lung adenocarcinoma cells (CALU-3, ATCC, HTB-55)¹⁸ with a specific activity of 35,000 IU/mg. M_r 32,000 scu-PA (scu-PA-32k) with a specific activity of 71,000 IU/mg was obtained from this same cell line as described elsewhere.¹⁵ Prior to use all three forms of scu-PA were freed of contaminating urokinase by chromatography on benzamidine-sepharose,²⁰ which reduced the urokinase content to less than 1%. Urinary urokinase (Winkinase) was a gift from Dr E. Murano, Bureau of Biologics, Bethesda, MD.

Human fibrinogen²¹ and thrombin²² were prepared by the methods described. Fibrinogen labeling with ^{125}I (Amersham Research

Products, Amersham, UK) was performed with the Enzymobead Reagent (Biorad, Richmond, CA). Desalting and purification were accomplished by filtration over a 10 mL column of Sephadex G25 (Pharmacia, Uppsala, Sweden) and a 0.7×60 cm column of Ultrogel AcA 44 Ultrogel (LKB, Bromma, Sweden) respectively.

In vitro lysis of human plasma clots. The relative fibrinolytic and fibrinogenolytic properties of the different forms of scu-PA and of urokinase were determined in an in vitro system consisting of a ^{125}I -labeled human plasma clot immersed in citrated human plasma, as previously described.²³ The ^{125}I -labeled plasma clots were added to 2.5 mL aliquots of pooled plasma, counted, and warmed to 37°C in a water bath. Fifty microliters of plasminogen activator were then added. At one-hour intervals, 250 μL of plasma were removed, the ^{125}I content measured, and the percent lysis determined from the solubilized radioisotope. Controls without added plasminogen activator were determined at each hourly sampling point and always were less than 5% to 10% of total releasable radioactivity over the four-hour experimental period. Plasma fibrinogen levels were determined immediately on each hourly sample,²⁴ and α_2 -antiplasmin levels were later measured on frozen samples.²⁵ Reported results are means of at least three separate experiments.

The stability of the plasminogen activators in plasma was measured in the following way. Mixtures were incubated at room temperature for varying periods of time with concentrations of plasminogen activator chosen to give at least 50% lysis within four hours. After pre-incubation, freshly prepared ^{125}I -labeled plasma clots were added to the mixtures that were placed at 37°C . Lysis rates were measured and calculated as above on duplicate samples.

Thrombolysis in a rabbit jugular vein thrombosis model. The in vivo thrombolytic properties of cellular scu-PA and scu-PA-32k were compared to those of urokinase in the rabbit jugular vein thrombosis model previously described.²⁶ In the present study ^{125}I -labeled jugular vein thrombi were aged for 30 minutes, then the plasminogen activator was administered as a 10% bolus injection, followed by continuous infusion of the remaining 90% dose over four hours via a contralateral marginal ear vein. Thrombolysis was quantitated 30 minutes after the end of the infusion by counting the residual radioactivity in the jugular vein segment. Blood samples of 1 mL were drawn into 0.01 mol/L citrate and used for determinations of residual fibrinogen and α_2 -antiplasmin levels.

RESULTS

The dose response of fibrinolysis in human plasma in vitro of the three forms of scu-PA and of urokinase is shown in Fig 1. Urinary scu-PA induced significant clot lysis at a concentration of 200 IU/mL in two to three hours (Fig 1A). At a twofold higher concentration, more rapid lysis occurred, 35% within one hour and 95% within two hours. No significant lysis was observed over the four-hour observation period at concentrations below 100 IU/mL. Similar dose-related fibrinolytic responses were also seen with cellular scu-PA (Fig 1B) and scu-PA-32k (Fig 1C), with significant lysis occurring with 100 IU/mL or more and to lysis with 50 IU/mL or less. Lysis progressed with time with all three molecular forms of scu-PA. When lysis induced by urokinase was quantitated (Fig 1D), initially a more rapid and more potent effect was seen. The addition of only 50 IU/mL induced 50% lysis within one hour. This rapid initial lysis was proportional to the amount of urokinase added, but in contrast to that observed with the scu-PA forms, the subsequent lysis rates decreased with time. With urokinase, lysis thus occurred predominantly within the first two hours.

The relative fibrin-specificities of the urokinase-type plas-

Fig 1. Lysis of human plasma clots labeled with ^{125}I fibrin following addition of (A) urinary scu-PA (●—●: 50 IU/mL; ■—■: 100 IU/mL; ◆—◆: 200 IU/mL; ▼—▼: 400 IU/mL). (B) cellular scu-PA (●—●: 20 IU/mL; ■—■: 40 IU/mL; ◆—◆: 80 IU/mL; ▼—▼: 160 IU/mL). (C) scu-PA-32k (●—●: 12 IU/mL; ■—■: 24 IU/mL; ◆—◆: 48 IU/mL; ▼—▼: 95 IU/mL; ▼—▼: 190 IU/mL). (D) urokinase (●—●: 12 IU/mL; ■—■: 24 IU/mL; ◆—◆: 48 IU/mL; ▼—▼: 96 IU/mL). Control values without added plasminogen activator were: at one hour: $3.7\% \pm 1.3\%$; at two hours: $5.6\% \pm 1.7\%$; at three hours: $6.7\% \pm 2.3\%$; at four hours: $7.0\% \pm 3.1\%$. Each data point represents the mean value of at least three separate experiments $\pm$ SD for one concentration of each giving significant lysis.

minogen activators (u-PAs) are shown in Fig 2. At concentrations of 200 IU/mL (urinary), 160 IU/mL (cellular), or 95 IU/mL (scu-PA-32k) 50% or more lysis was observed within four hours, all with less than 25% fibrinogen breakdown. At concentrations of 400 IU/mL of urinary scu-PA (Fig 2A) or of 200 IU/mL of scu-PA-32k (Fig 2C), which gave 100% after three hours, plasma fibrinogen levels decreased to below 25% of the baseline level. With urokinase (Fig 2D), 45% to 55% lysis occurred after one hour with both 48 and 96 IU/mL, concomitant with 30% and 70% fibrinogen degradation respectively. At a concentration of 96 IU/mL urokinase was also associated with a greater than 75% decrease in fibrinogen levels after two hours while not causing 100% lysis even after four hours. Thus, although none of the urokinase-type plasminogen activators was absolutely fibrin-specific in this in vitro model, equivalent clot lysis appeared to be accompanied by less extensive fibrinogen degradation with all three single-chain forms. Measurement of α_2 -antiplasmin levels confirmed this, with less than 50% consumption associated with 50% lysis by the three single-chain forms, while 50% lysis by urokinase was always accompanied by greater than 50% α_2 -antiplasmin consumption (not shown).

Fig 2. Plasma fibrinogen levels during lysis of human plasma clots labeled with ^{125} I-fibrin following addition of urinary scu-PA (A); cellular scu-PA (B); scu-PA-32k (C); and urokinase (D). The symbols represent the same concentrations as in Fig 1. Control fractional fibrinogen levels without added plasminogen activator were at one hour: 0.99 ± 0.025 ; at two hours: 0.92 ± 0.059 ; at three hours: 0.96 ± 0.034 ; and at four hours: 0.90 ± 0.045 . Each data point represents the mean value of at least three separate experiments $\pm$ SD for one concentration of each giving significant lysis.

The relative stability of scu-PA in plasma was illustrated by pre-incubation studies with results shown in Fig 3. Lysis of freshly prepared plasma clots was measured after pre-incubation of mixtures of plasma with each of the four forms of u-PA at room temperature. Without preincubation all three single-chain forms, at concentrations between 160 and 400 IU/mL, gave 50% lysis within 1.5 to 2.5 hours. The more

Fig 3. Lysis of freshly prepared human plasma clots labeled with ^{125} I-fibrin after pre-incubation with urinary scu-PA 400 IU/mL ($\blacksquare$); cellular scu-PA 160 IU/mL ($\blacklozenge$); scu-PA-32k 190 IU/mL ($\blacktriangledown$); urokinase 48 IU/mL ($\bullet$); and control without added plasminogen activator ($\circ$). (A) 0 hours; (B) 24 hours; (C) 48 hours. Each data point represents the mean of two experiments.

rapid initial rate for urokinase was evident by 50% lysis with 48 IU/mL at only one hour (panel A). After pre-incubation for 24 hours (panel B) and 48 hours (panel C), the potency of the single-chain forms was largely maintained, with 50% lysis still occurring within 2.5 to 4 hours. In contrast, urokinase was completely inhibited within the first 24 hours.

The thrombolytic properties and the fibrin specificity of the more readily available cellular scu-PA and scu-PA-32k were compared with those of urokinase in a rabbit jugular vein thrombosis model with results summarized in Table 1. Lysis measured 30 minutes after the end of infusion of solvent into control animals was $8.9\% \pm 0.6\%$. Dose-dependent lysis (12% to 48%) was observed for urokinase over a range of 20,000 to 200,000 IU (0.2 to 2.0 mg) per kilogram. A similar range of lysis (13% to 40%) was produced by infusion of cellular scu-PA over a concentration range of 8,700 to 35,000 IU (0.25 to 1.0 mg) per kilogram and by scu-PA-32k between 9,000 and 36,000 IU (0.13 to 0.5 mg) per kilogram. Comparable thrombolysis (20% to 25%) was obtained with 100,000 IU/kg urokinase, 17,000 IU/kg scu-PA, and 18,000 IU/kg scu-PA-32k, ie, five- to eightfold lower total doses for both forms of scu-PA than for urokinase. In addition, both forms of scu-PA failed to induce systemic fibrinolytic activation, as evidenced by normal

Table 1. Thrombolysis After Infusion of Different Molecular Forms of scu-PA or Two-Chain Urokinase in Rabbits With Jugular Vein Thrombosis

Agent	Dose (IU/kg)	n	Lysis (percent)	Recovery (percent)	Fibrinogen (percent)	α_2 -Antiplasmin (percent)
Control	—	5	8.9 ± 0.6	99 ± 1.8	101 ± 3	94 ± 4
Urokinase	20,000	3	12 ± 0.8	99 ± 1.5	101 ± 5	90 ± 6
	50,000	3	16 ± 2.3	94 ± 2.2	95 ± 5	87 ± 2
	100,000	3	22 ± 0.8	95 ± 0.9	91 ± 7	74 ± 6
	200,000	4	48 ± 4.3	93 ± 5.3	39 ± 24	42 ± 14
Cellular scu-PA	8,700	3	13 ± 1.3	94 ± 1.0	92 ± 12	92 ± 7
	17,000	6	21 ± 1.4	94 ± 1.8	99 ± 3	85 ± 3
	35,000	4	34 ± 3.8	88 ± 1.8	92 ± 2	97 ± 4
scu-PA-32K	9,000	3	15 ± 1.1	96 ± 1.0	98 ± 2	90 ± 8
	18,000	3	24 ± 1.5	94 ± 3.3	99 ± 4	95 ± 2
	36,000	3	40 ± 4.1	93 ± 3.2	90 ± 5	100 ± 2

Each figure represents the mean $\pm$ standard error of the mean of the number of experiments indicated by n.

fibrinogen and α_2 -antiplasmin levels. Lysis with urokinase occurred with less fibrin-specificity as reflected by the dose-dependent consumption of α_2 -antiplasmin. Fibrinogen degradation with urokinase was very pronounced at the highest dose (200,000 IU/kg) with plasma levels falling to 39% of baseline.

DISCUSSION

Evidence is accumulating that the single-chain form of urokinase, presently designated scu-PA,¹⁶ shows potential as a fibrin-specific thrombolytic agent. Although scu-PA isolated from its natural source, human urine, has been characterized to some extent,^{16,17} all information on its fibrin specificity in plasma *in vitro*^{8,9} or *in vivo*^{7,8,10-12} has been obtained with material isolated from secondary sources, eg, cell culture or recombinant DNA technology. In the present study we compared the specific thrombolytic properties of scu-PA derived from human urine, its natural biological source, with that of scu-PA isolated from CALU-3-conditioned cell culture media. Both forms of scu-PA do induce clot lysis with relatively higher fibrin specificity than urokinase in a human plasma milieu. In addition, both scu-PA forms demonstrate relatively higher stability in plasma than urokinase, with an approximately 50% preservation of fibrinolytic capacity after 48 hours incubation of scu-PA with plasma but total inhibition of urokinase within 24 hours. This relative stability, as previously recognized for scu-PA from other secondary natural⁸ or recombinant sources,⁹ has been ascribed to the presence of specific plasma inhibitor(s) of urokinase. Such an inhibitor has in fact now been identified in human plasma with inhibitory activity toward urokinase but not scu-PA.²⁷ This inhibition would not account for the partial reduction in fibrinolytic activity of the single-chain forms seen during pre-incubation, though some loss of activity after prolonged room temperature exposure is perhaps not surprising.

From these observations two extrapolations can be made. First, since scu-PA circulating in blood²⁸ is most likely identical to that isolated from urine, it may as such contribute to physiologic fibrin-specific thrombolysis via its relatively unique fibrinolytic properties. Second, scu-PA from cellular origin, specifically isolated from CALU-3-conditioned cell culture media, having biological properties identical to those of urinary scu-PA, may constitute a valid and

more practical alternative for the study of the biochemical and biological properties of scu-PA.

In addition, the *in vitro* and *in vivo* thrombolytic properties of scu-PA-32k, a previously unrecognized molecular form of scu-PA, were compared with that of its well-characterized M_r 54,000 counterpart. Though structurally different, both forms induced very similar clot lysis, relatively distinct from that of urokinase. Their molar-specific fibrinolytic activities, as measured on fibrin plates, were identical, although their thrombolytic potency *in vivo* was higher than that of urokinase, as contrasting with the higher *in vitro* potency of urokinase. This discrepancy may well be related to species differences between the plasma systems utilized, especially with the known lack of sensitivity of the rabbit to urokinase.²⁹

While our results indicate that the moiety(ies) responsible for the fibrin specificity of scu-PA are not dependent upon the NH_2 -terminal and kringle-containing portions of the M_r 54,000 protein, which are indeed absent in scu-PA-32k,¹⁹ the exact structures responsible for its unique action remain, however, to be more precisely defined. Since scu-PA appears to act more via a high affinity for its natural substrate plasminogen than via a specific affinity for fibrin, it is perhaps not surprising that the domains responsible for lysine (fibrin) binding could be deleted without any impact on the fibrinolytic capacity of the enzyme. In fact, scu-PA-32k does display the same high affinity for plasminogen ($K_m = 0.9 \mu\text{mol/L}$) as M_r 54,000 scu-PA, a property not present in either molecule following conversion to two-chain u-PA by cleavage of the Lys 158-Ile 159 peptide bond.¹⁹ In any case, scu-PA-32k, a low M_r variant of scu-PA with identical thrombolytic properties, may constitute a more practical alternative to the native high M_r form, particularly for the large-scale production of this thrombolytic agent by recombinant DNA technology. As such it may offer significant potential for future development.

In summary, it is concluded that scu-PA derived from its natural biological source, human urine, has distinctive fibrinolytic properties from urokinase. Furthermore, the more readily available scu-PA, obtained from CALU-3 cell structures, has identical thrombolytic properties to the material of urinary origin. Thus, scu-PA and scu-PA-32k, a proteolytic derivative of scu-PA, may constitute valid alternatives for future physiologic and therapeutic studies in man.

Hematologic Engraftment and Immune Reconstitution Posttransplantation With Anti-B1 Purged Autologous Bone Marrow

By K.C. Anderson, J. Ritz, T. Takvorian, F. Coral, H. Daley, B.C. Gorgone, A.S. Freedman, George P. Canellos, S.F. Schlossman, and L.M. Nadler

Hematologic engraftment and immune reconstitution were examined in patients who received cyclophosphamide and total body irradiation therapy followed by infusion of autologous bone marrow purged with anti-B1 monoclonal antibody (MoAb) and complement as therapy for non-Hodgkin's lymphoma. Hematologic engraftment was prompt with return of $\geq 0.5 \times 10^3/\mu\text{L}$ granulocytes and $\geq 2 \times 10^4/\mu\text{L}$ platelets at a median of 26 and 29 days posttransplant, respectively. Immunologic reconstitution, in contrast, was prolonged. Normal numbers of circulating B cells were consistently noted by five months posttransplant, whereas return of normal immunoglobulin levels in some patients did not occur for one year. Normal numbers of T cells were

evident within the first month posttransplant, but a reversed T4:T8 ratio persisted in some patients up to three years. In vitro responses of either B cells to triggers of activation or of T cells to mitogens and antigens were not normal for at least three months posttransplant. Natural killer (NK) cells predominated early after transplant and may demonstrate cytotoxicity against tumor cells. Our studies demonstrate that transplantation with anti-B1 purged autologous bone marrow results in complete hematologic and delayed immunologic engraftment. No significant acute or chronic clinical toxicities have been observed.

© 1987 by Grune & Stratton, Inc.

HIGH-DOSE chemoradiotherapy and bone marrow support now have become an important treatment modality for patients with relapsed non-Hodgkin's lymphoma (NHL).¹ Although earlier studies employed syngeneic^{2,3} or allogeneic⁴⁻⁷ bone marrow to rescue the aplasia induced by ablative therapy, most recent trials now employ autologous marrow.⁸⁻²¹ This approach has demonstrated high efficacy with complete responses approaching 90% and minimal toxicity compared with allogeneic transplantation. A more general application of autologous bone marrow transplantation (ABMT) for NHL has been limited by lymphomatous infiltration of the marrow.²²⁻²⁶ To overcome this obstacle, several approaches to purge the marrow of tumor cells have been suggested. These include techniques to remove tumor cells on the basis of their density, osmotic fragility, sensitivity to chemotherapy, and/or expression of tumor-associated cell surface antigens.²⁷ However, the success of these techniques, either alone or in combination, is dependent upon the removal of tumor cells from the marrow without damaging hematopoietic stem cells.

The eradication of lymphoma cells from the bone marrow of patients with relapsed B cell NHL has been one of our major interests during the past 3½ years. We have treated minimally involved bone marrows of patients with relapsed B cell NHL with the monoclonal antibody (MoAb) anti-B1 and rabbit complement in an attempt to render the marrow tumor free.^{1,13,21} The anti-B1 MoAb defines a nonglycosylated phosphoprotein of 35kD whose expression within the hematopoietic system appears to be B cell restricted.²⁸⁻³⁰ This antigen appears on the B cell surface prior to the cytoplasmic μ positive pre-B cell stage and is lost from the cell surface as cells become plasma cells. Detailed in vitro experiments demonstrated that the B1 antigen is not expressed on either myeloid or erythroid stem cells.³¹ Moreover, treatment with anti-B1 MoAb and complement in vitro eliminates clonogenic Burkitt's cells from normal human bone marrow.³²

Although hematologic engraftment in our patients who received anti-B1-purged ABMT has been rapid and complete, it is equally important to demonstrate immunologic engraftment. Relapsed lymphoma patients rescued with untreated autologous bone marrow have demonstrated rapid resolution of granulocytopenia and thrombocytopenia by

three to four weeks post-ABMT.^{8-11,18} However, the reconstitution of immune function following ABMT for lymphoma has been less well studied. We have therefore attempted to examine both hematologic and immunologic engraftment of patients who have undergone ABMT after purging of marrow tumor cells with anti-B1 MoAb and complement.

MATERIALS AND METHODS

Hematologic Engraftment

Peripheral blood samples obtained from 24 patients who underwent autologous bone marrow transplantation therapy are included in this analysis: 23 patients with NHL and a single patient with chronic lymphocytic leukemia. Prior to in vitro marrow purging, patients were treated with conventional chemotherapy, radiation therapy, and/or surgery to a minimal tumor burden and a histologically uninvolved bone marrow with <5% cells expressing B1. To date all patients have attained a complete clinical response and have achieved complete hematologic engraftment with minimal acute and chronic clinical toxicity. The day posttransplant, when circulating white blood cells appeared, as well as the interval to achievement of $\geq 0.5 \times 10^3$ granulocytes/ μL and a stable untransfused platelet count of at least $2 \times 10^4/\mu\text{L}$ served as monitors of hematologic

engraftment. The duration of hospitalization posttransplant was also recorded.

Patient Samples

After appropriate human protection validation and informed consent, patient samples were obtained for study. Peripheral blood samples were obtained prior to and at various intervals posttransplantation. Mononuclear cells were obtained from peripheral blood (PBMCs) by Ficoll-Hypaque density sedimentation³³ for phenotypic and functional analysis. Sufficient numbers of cells were not available for every time point; in particular, detailed data were not collected for the earliest patients undergoing this treatment. In addition, no analysis was performed beyond the time of relapse for nine patients.

Phenotypic Analysis

A panel of MoAbs specific for B and T cells, monocytes, and natural killer (NK) cells was used in this study (Table 1). PBMCs were assayed for reactivity with the MoAbs by indirect immunofluorescence staining and flow cytometric analysis as described previously.³⁴ Antibody-coated cells were enumerated by flow cytometric analysis using an EPICS V cell sorter (Coulter Electronics, Hialeah, FL). For each sample 10,000 cells were analyzed using a log amplifier.

Functional Assays

Peripheral blood samples (60 mL) were obtained from patients and at least one normal donor at the time of each functional assay.

Stimulation of B Cells

B cell proliferation assays were performed as previously described.⁴² B cell-enriched preparations were made from PBMCs by E rosette depletion whenever numbers of cells permitted. Because it is extremely difficult to purify B cells from peripheral blood to homogeneity using both depletion as well as enrichment techniques,⁴² we chose anti-u, which is a stimulus for B cell but not for T cell proliferation.⁴²⁻⁴⁴ Cells were resuspended at 5×10^5 cells/mL in RPMI/10% fetal calf serum, and 100- μ L aliquots were dispensed in 96-well round-bottomed tissue culture plates (Costar, Cambridge, MA). Cells were cultured in the presence of either rabbit anti-u chain-conjugated polyacrylamide beads (30 μ g/mL, wt/vol) (Immunobead, BioRad, Richmond, CA) or media to a final culture volume of 200 μ L/well. To measure proliferation, some cultures were pulsed at 48 hours with 0.2 μ Ci/well (1 Ci = 3.7×10^{10} Bq) of

tritiated thymidine ($[^3\text{H}]\text{TdR}$), were harvested 15 hours later onto glass filters, and were counted on a liquid scintillation counter (Packard Tri-Carb 4530, Downers Grove, IL). A stimulation index (proliferation noted to a given stimulus/proliferation noted to media alone) ≥ 2.0 was judged to be significant. B cells from normal donors were stimulated at the time of each patient assay and served as controls.

Stimulation of T Cells

PBMCs were resuspended at 1×10^6 cells/mL in RPMI/10% human AB serum, and 100 μ L aliquots were dispensed in 96-well, round-bottomed tissue culture plates (Costar). Cells were cultured in the presence of either media alone or stimuli at the following final concentrations: phytohemagglutinin (PHA) 1:5 and 1:10; concanavalin A (Con A) 1:20 and 1:40; mumps 1:20; tetanus toxoid 1:10; and *Candida albicans* 1:50. For allogeneic mixed-lymphocyte reactions, Epstein-Barr virus (EBV)-transformed Laz 388 cells were irradiated to 5,000 R, resuspended at 1×10^6 /mL, and 100- μ L aliquots dispensed into 96-well round-bottomed plates containing equal numbers of patient PBMCs. Twenty microliters of T cell growth factor containing media (TCGF-CM) was also added to wells already containing patient cells and/or media, PHA, or Laz 388 cells. In all cases cells were cultured at 37 °C in 5% CO₂ and pulsed with 0.2 μ Ci/well (1 Ci = 3.7×10^{10} Bq) of tritiated thymidine ($[^3\text{H}]\text{TdR}$), harvested 18 hours later, and counted as described above. The increment in proliferation noted to the individual stimulus compared to media was calculated for both the patient and for the normal control examined on the same day. The patient response to any given stimulus was judged to be significant if it was $\geq 40\%$ of proliferation of normal cells cultured with the identical stimulus. Finally, proliferation noted to PHA or Laz 388 was compared to that noted when cells were cultured with these stimuli supplemented with TCGF-CM. The addition of TCGF-CM to PHA was judged to significantly enhance proliferation if proliferation to TCGF-CM and PHA/proliferation to PHA ≥ 1.5 . The TCGF-CM used in these studies was obtained as previously described.⁴⁵

Cytotoxicity (Natural Killer Cell) Assays

Cytotoxicity assays were performed according to a standard chromium release method previously described.⁴⁵ Assays were performed at various effector:target ratios using 5,000 K562 target cells/well. Significant NK cell function was $>5\%$ killing of K562, as evidenced by chromium release assay.

RESULTS

Hematologic Engraftment

A median of 5.1 (range 2.0 to 8.5×10^7) autologous bone marrow cells/kg were reinfused. Marrow engraftment occurred in all patients with the first evidence of white blood cell recovery generally by days 10 to 12 and 0.5×10^3 granulocytes/ μ L at a median of 26 (range 12 to 45) days after transplant. A stable nontransfused platelet count of at least 2×10^4 / μ L was attained at a median of 29 (range 14 to 137) days. Finally, duration of hospitalization was a median of 33 (range 20 to 58) days posttransplant. Eighty-four percent, 10%, and 6% of deglycerolized frozen red blood cells were transfused in the first, second, and third months posttransplant, respectively. Eighty percent of platelets were transfused in the first month, 19.5% in the second month, and only 0.5% after eight weeks posttransplant.

Table 1. Reactivity of Monoclonal Antibodies

Monoclonal Antibody	CD	Lineage Restriction	Molecular Weight (kilodaltons)	Reference
Anti-B4	19	Pan-B	95	34
Anti-B1	20	Pan-B	35	29, 30
Anti-B2	21	Limited-B (EBV/C3d receptor)	140	35
Anti-T3	3	Mature T (Part of T3-Ti T cell receptor/complex)	19-29	36
Anti-T11	2	Pan-T (Alternative pathway of T cell activation)	50	36

NK cells	4/10	6/7	7/11	9/13	8/13	3/9	5/7	4/6	3/5	0/4	2/5	2/3
Monocytes	12/14	1/8	5/13	11/15	10/15	7/9	5/6	6/6	4/5	4/4	4/4	3/3

*Normal numbers of cells were as follows: 5% to 10% PBMCs reactive with anti-B1, anti-B2, or anti-B4 (B cells); 60% to 75% PBMCs reactive with anti-T3 and/or anti-T11 (T cells); 10% PBMCs reactive with anti-901 or anti-NH₁ (NK cells); 10% to 15% PBMCs reactive with anti-Mo2 (monocytes). Normal T4:T8 ratio is 1.5 to 2.5.

†Two of the three patients have been repeatedly tested during this interval.

Immunologic Engraftment

Phenotypic Analysis

A panel of MoAbs directed at B and T cells, monocytes, and natural killer (NK) cells (Table 1) was utilized in an indirect immunofluorescence assay to monitor the phenotype of PBMCs as bone marrow engraftment and reconstitution of peripheral blood leukocytes proceeded (Table 2).

B cells. Normal numbers of B lymphocytes, as reflected by reactivity with anti-B1, anti-B2, and/or anti-B4 MoAbs, were present in six of 14 patients examined before transplantation. Cells bearing these antigens were totally absent in ten patients at two weeks and present in only one of 14 patients at three weeks post-ABMT. At one month post-ABMT, 27% (four of 15) patients had normal B cells: two of these patients had multiply relapsed lymphoma, and two patients were less heavily pretreated since they were transplanted earlier in the course of their disease. By eight to 16 weeks posttransplant, approximately 50% of patients demonstrated normal percentages of B1⁺, B2⁺, and/or B4⁺ cells, and at ≥20 weeks post-ABMT all patients studied had normal numbers of B lymphocytes.

T cells. Total T cells were enumerated by reactivity with anti-T3 and/or anti-T11 MoAbs. Only 21% (three of 14) patients had normal numbers of T cells prior to ABMT. Within two to four weeks of reinfusion, ≥60% of the mononuclear cells expressed T3 and/or T11. Many of the T11⁺ or T3⁺ cells noted early after transplant are large granular

lymphocytes that co-express cell surface NKH1. As B cells and monocytes reappear and increase in number beginning at three to four weeks post-ABMT, the percentage of T11⁺ cells decreases. The T4:T8 ratio (normal 1.5 to 2.5) remains abnormal in some patients beyond one year post-ABMT due to both a decrease in T4⁺ helper/inducer cells as well as an increase in T8⁺ cytotoxic/suppressor cells.

NK cells. Natural killer (NK) cells, which express the NKH1 antigen, were ≥10% PBMCs in only 40% (four of 11) of patients examined prior to ABMT. However, within the first month following ABMT, the overwhelming majority of patients had increased numbers of cells (up to one third of PBMCs) expressing the NK phenotype. In some cases this increased percentage of cells with NK cell phenotype persisted to one year posttransplant.

Monocytes. Monocytes (Mo2⁺) composed ≥15% PBMCs in 86% of patients tested prior to transplant, in five of 13 patients at three weeks post-ABMT, and in ≥2/3 of patients tested beyond one month following ABMT.

Functional Analyses

B cell proliferation. B cell-enriched populations were obtained at various intervals post-ABMT and examined for their responsiveness to anti-u, a known B cell specific mitogen (Table 3). Two of four patients tested prior to transplant demonstrated significant proliferation [stimulation index (SI) ≥2.0] to anti-u bound to polyacrylamide

Table 3. B Cell Stimulation*

Response	No. Patients Responding/No. Patients Tested			
	Pre	Weeks Posttransplant		
		0-4	4-8	12-116†

*B cell-enriched populations were suspended at 5×10^5 cells/mL in RPMI/10% fetal calf serum, and 100-μL aliquots were dispensed in 96-well round-bottomed tissue culture plates. Cells were cultured in the presence of either rabbit anti-u chain-conjugated polyacrylamide beads (30 μg/mL, wt/vol) or media. Cultures were pulsed 48 hours later with tritiated thymidine ($[^3\text{H}]\text{TdR}$) and harvested and counted 15 hours later. Counts per minute of $^3\text{H-TdR}$ in cultures with media alone were as follows: pre, 161-500; zero to four weeks, 320-947; four to eight weeks, 413-1126; and 12 to 116 weeks, 192-877.

†Five patients were repeatedly tested during this time interval.

beads. Of nine and eight patients tested at zero to four and four to eight weeks post-ABMT respectively, none demonstrated significant proliferation. By 12 to 116 weeks post-ABMT, B cells from nine of ten patients again proliferated to anti-u.

Serum immunoglobulin (Ig) levels. Serum IgG, IgA, and IgM levels were normal in the majority of patients tested prior to and at four weeks post-ABMT ($\geq 6/13$ and $\geq 6/10$ patients, respectively) (Table 4). By eight to 20 weeks post-ABMT, a minority of patients had normal Ig levels. At 24 to 52 weeks post-ABMT, $\geq 50\%$ of patients had reconstituted normal serum Ig levels, and nearly all patients tested one year post-ABMT had normal levels of IgG, IgA, and IgM.

T cell proliferation. PBMCs were cultured in the presence of mitogens, antigens, or growth factors known to trigger T lymphocyte proliferation. Responses were considered to be positive if the proliferation to a given T cell stimulus was $\geq 40\%$ of the increment noted in a normal donor's cells cultured under identical conditions. As can be seen in Table 5, approximately 50% of patients examined prior to transplant responded to phytohemagglutinin (PHA) or concanavalin A (Con A). Responses to either mitogen were absent for a two-month period post-ABMT. In four of ten patients tested at 12 to 116 weeks posttransplant, T cell responses were again noted to either mitogen. Antigen-specific assays for the stimulation of T cell proliferation included mumps, tetanus toxoid, and *Candida albicans*. As was true for both PHA and Con A, only 50% of patients examined prior to ABMT responded to these antigens. Within the first month posttransplant, residual responsiveness was noted in 22% to 44% of patients tested. However, responses were largely absent by the second month posttransplant, and only two of ten patients tested at ≥ 12 weeks responded to these antigens.

T cell growth factor containing medium (TCGF-CM) obtained by stimulating PBMCs with PHA, phorbol myristate acetate, and irradiated allogeneic (Laz 388) cells was also utilized to stimulate the proliferation of patients' PBMCs obtained at various intervals post-ABMT. The majority of patients responded to TCGF-CM both before and within the first four weeks after transplantation. Although only two of seven patients' cells responded to TCGF-CM in the second month posttransplant, the majority (70%) of patients again were responsive at 12 to 116 weeks. For allogeneic mixed-lymphocyte reactions (MLR), EBV-

*The increment in ^3H thymidine uptake by cells cultured with stimulus compared to cells cultured in media alone was calculated. A patient was judged to have demonstrated a response if the increment was $\geq 40\%$ of the increase in proliferation noted in cells obtained from a normal donor cultured with the same stimulus under identical conditions.

†T cell growth factor-containing medium was obtained by stimulating unfractionated peripheral blood mononuclear cells with phytohemagglutinin, phorbol myristate acetate, and irradiated allogeneic (Laz 388) cells.

‡Epstein-Barr virus (EBV)-transformed Laz 388 cells were irradiated and cultured with equal numbers of patient peripheral blood mononuclear cells.

transformed Laz 388 cells were irradiated and cultured with equal numbers of patients' PBMCs. As was true for cultures with TCGF-CM, the majority of patients' PBMCs examined before and in the first month after transplant proliferated in MLR. Responsiveness of PBMCs to allogeneic Laz 388 cells was present in 57% and 80% of patients tested at four to eight weeks and at 12 weeks posttransplant respectively.

We next examined whether proliferation of cells to the combination of TCGF-CM + PHA was enhanced (≥ 1.5 -fold) relative to that noted to either TCGF-CM or PHA alone (Table 6). The majority ($\geq 88\%$) of patients tested both before and at ≥ 12 weeks post-ABMT demonstrated prolifer-

Table 6. T Cell Proliferation*

Patient Response	No. Patients Responding/No. Patients Tested			
	Weeks Posttransplant			
	Pre	0-4	4-8	12-116
TCGF + PHA ≥ 1.5	7/8	3/9	4/7	9/10
TCGF + PHA ≥ 1.5	8/8	3/9	4/7	3/10
Laz 388 + TCGF ≥ 1.5	7/8	4/9	6/7	9/10
Laz 388 + TCGF ≥ 1.5	7/8	7/9	4/7	7/10
Laz 388	8/8	9/9	7/7	10/10

*20 μL of T cell growth factor containing media (TCGF-CM) was added to wells already containing patient cells and/or media, phytohemagglutinin (PHA), or Laz 388 cells. The addition of TCGF-CM to PHA or Laz 388 was judged to significantly enhance proliferation if it increased proliferation by 50% compared to the proliferation noted to PHA or Laz 388 alone.

ation to TCGF-CM + PHA: proliferation to PHA ratio ≥ 1.5 . In contrast, within the first two months posttransplant $\leq 50\%$ of patients manifested a greater response to TCGF-CM + PHA than to PHA alone. All eight patients examined prior to transplant had significantly increased proliferation to TCGF-CM + PHA relative to TCGF-CM alone. However, the addition of PHA to TCGF-CM did not significantly increase proliferation relative to that noted to TCGF-CM alone in the majority of patients examined up to 116 weeks posttransplant.

In a similar fashion we tested whether patients' PBMCs proliferated to a greater extent to TCGF-CM + allogeneic (Laz 388) cells than to either of these stimuli alone. Nearly all patients tested before and at ≥ 12 weeks posttransplant (seven of eight and nine of ten patients respectively) demonstrated increased proliferation to Laz 388 cells + TCGF-CM compared to TCGF-CM alone. Similarly, most ($\geq 70\%$) patients examined before and at ≥ 12 weeks posttransplant augmented proliferation to Laz 388 cells + TCGF-CM compared to Laz 388 cells alone. At one and two months posttransplant, 44% to 77% of patients also proliferated to a greater extent to the combination of TCGF-CM + Laz 388 cells than to either stimulus alone.

Natural killer cell function. Cytotoxicity assays were performed using effector cell (patient's PBMCs): target cells (K562 chronic myelogenous leukemia) ratios of 7.5 to 60:1. Significant killing was evidenced by $>5\%$ of maximal $^{51}\text{chromium}$ release from radiolabeled target cells. As can be seen in Table 7, all six patients tested prior to transplantation demonstrated natural killer (NK) cell function. Early (zero to four weeks) after transplant cytotoxicity was noted in seven of 11 patients tested. All patients tested at four to eight weeks and ≥ 12 weeks (seven and nine patients respectively) post-ABMT had normal NK cell function. In each case maximal killing was seen at effector: target ratios of 60:1.

Natural killer cell killing against autologous tumor cells was examined in a single patient at one-month post-ABMT. Twenty-two percent of the patient's PBMCs were NK cells by virtue of staining with anti-NKH1 MoAb at this time. Cryopreserved tumor cells were radiolabeled with $^{51}\text{chromium}$, and 19% maximal $^{51}\text{chromium}$ release was noted at patient's PBMCs (effector):cryopreserved autologous tumor cell (target) ratios of 20 to 40:1.

DISCUSSION

In the present report we have examined both hematologic engraftment and immunologic reconstitution in recipients of autologous bone marrow purged with anti-B1 MoAb and complement. Hematologic engraftment was prompt with return of $\geq 0.5 \times 10^3/\mu\text{L}$ granulocytes and $\geq 2 \times 10^4/\mu\text{L}$ platelets at a median of 26 and 29 days posttransplant, respectively. Virtually all blood product support was complete by eight weeks posttransplant. In contrast to hematologic engraftment, immunologic reconstitution was prolonged. As expected, anti-B1 and complement marrow treatment completely eradicated detectable B cells as well as totally abrogating normal B cell function in vitro and in vivo. Normal numbers of circulating B cells consistently returned by five months post-ABMT, whereas return of immunoglo-

*Assays were performed at effector:target ratios of 7.5 to 60:1 using 5,000 K562 target cells/well. Greater than 5% maximal chromium release was judged as significant killing of target cells.

bulins in some patients did not occur for one year. Concomitant with the appearance of normal numbers of circulating B cells was the return of in vitro responses of B cells to triggers of activation (anti-u). Although normal numbers of T cells were evident within the first several months post-ABMT, a reversed T4:T8 ratio persisted in some patients indefinitely (up to three years). Moreover, in vitro responses to T cell mitogens and specific antigens were again not normalized for at least three months. Phenotypically and functionally defined NK cells appear to have a relative growth advantage early after transplant. These studies demonstrate that anti-B1 purged autologous bone marrow can result in complete hematologic and immunologic engraftment, although T and B cell engraftment appears to be prolonged. Most importantly, the time to hematologic and immunologic engraftment has not been associated with any significant acute or chronic clinical toxicities.

Overt or occult bone marrow involvement is very common at the time of relapse of NHL, regardless of the initial histology,²²⁻²⁶ and it therefore seemed important to develop methods to eradicate tumor cells from the marrow. We have attempted to purge tumor cells from the marrow using the pan-B cell MoAb anti-B1 and complement. To date, all patients have responded to the ablative therapy with a complete response and no acute toxicity, all have engrafted hematologically, and all were discharged from the hospital. Our patients achieved $\geq 0.5 \times 10^3$ granulocytes/ μL at a median of 26 (range 12 to 45) days post-ABMT, which is not significantly prolonged when compared to previous reports for nonpurged or pharmacologically purged autologous marrow.^{8-11,14,18} These results are slightly delayed when compared to recipients of syngeneic² or allogeneic⁶ marrow grafts, but it is important to note that autologous marrow in most instances had seen significant prior cytotoxic therapy. Moreover, although most patients developed fever during neutropenic periods, no increased numbers of bacterial ($n = 2$) or fungal ($n = 1$) septic infections were noted in our series compared to previously reported trials. Stable nontransfused platelet counts of at least $2 \times 10^4/\mu\text{L}$ were attained at a median of 29 (range 14 to 137) days in our series compared to recipients of syngeneic marrow who no longer required platelets at a median of 16 (range nine to 45) days² or to recipients of allogeneic and autologous transplants who achieved sustained untransfused platelet counts of $5 \times 10^4/\mu\text{L}$ at a median of 20 to 34 days respectively.^{8-11,14,18} In our series, 80% of platelets were transfused in the first month, 19.5% in the second month, and only 0.5% beyond eight weeks. There was not a single episode of clinically

significant bleeding. These results suggest that hematologic engraftment following anti-B1 purging is delayed but has not led to significant acute clinical toxicities.

The question of whether anti-B1 purging will become a more generalized treatment modality for patients with NHL will depend on the answers to two questions: first, and most important, is whether this purging technique can effectively deplete the clonogenic tumor cell; and second is whether the marrow purging affects engraftment sufficiently to produce clinical toxicity. The first question is still unanswered. Our results suggest that purging does not appear to produce significant clinical toxicity, which is surprising considering (1) the time to B and T cell engraftment observed in this study; and (2) the fact that many of our patients had abnormal numbers of B and T cells, NK cells, and T4:T8 ratio pretransplant attributable to their underlying disease and its chemotherapeutic treatment⁴⁶ as well as to multiple transfusions.⁴⁷ Less than 50% of recipients of anti-B1 purged autologous bone marrow have normal numbers of B cells either pretransplant or within the first two months post-ABMT, but all patients examined at ≥ 20 weeks post-ABMT have achieved normal numbers of phenotypically identified B cells. Fifty percent and 100% of our patients examined at ≥ 6 months and one year post-ABMT, respectively, achieved normal serum Ig levels, confirming the return of *in vivo* B cell function. Moreover, *in vitro* examination of B cells at ≥ 12 weeks post anti-B1 marrow purging also confirmed normal B cell responses to triggers of activation. Since the B1 antigen is expressed on 50% of pre-B cells in the marrow⁴⁸ and on virtually all mature B cells excluding the plasma cell,²⁸⁻³⁰ the delayed time to B cell engraftment in our patients suggests that many pre-B cells and most mature B cells have been eradicated by the *in vitro* purging and the *in vivo* ablative therapy. The present data do not permit us to determine whether the time to B cell engraftment is simply due to repopulation of B cell progenitors or whether it is also due to the defects in T cell reconstitution. Future studies of B cell reconstitution in the bone marrow may provide insight into this question.

Although return to normal B cell function *in vivo* requires approximately six months, it is important to note that infections associated with agammaglobulinemia have not been seen post-ABMT. B cell phenotype and function have been examined postallogeneic transplantation therapy for leukemia⁴⁹⁻⁵⁹; however, there have been few studies detailing B cell reconstitution postsyngeneic⁶⁰ or post-ABMT for leukemia^{54,56,61} and no similar studies post-ABMT for lymphoma. It is therefore difficult to determine whether B cell engraftment in our hands is significantly prolonged. Moreover, it is not possible to compare B cell engraftment post-ABMT with that noted after allogeneic transplant because of the immune dysregulation of graft-v-host disease (GVHD) and prolonged immune suppression by drugs in the majority of allogeneic studies as well as the immune defects following T cell depletion in more recent studies in recipients of allogeneic transplants. We have studied one patient who underwent an identical twin transplant for relapsed B cell lymphoma. In this case B cells returned between six and eight weeks and normal Ig levels were present by four months. This suggests that anti-B1 purging does prolong

engraftment, although it is important to note that the autologous bone marrow had seen significant prior cytotoxic therapy. Further studies of B cell reconstitution post-ABMT in patients who receive nonpurged marrows will be necessary to determine whether anti-B1 MoAb and complement treatment significantly impairs B cell function.

Whereas B cell immunosuppression did not result in clinical toxicity, T cell immunosuppression appears to result in increased episodes of Herpes Zoster. In our series approximately one third of patients who are disease free at ≥ 6 months have developed Zoster without a significant increase in other viral or fungal infections. Other investigators have noted interstitial pneumonitis and cytomegalovirus (CMV) infections in recipients of nonpurged autologous grafts that we have not observed to date.⁶² These specific immune defects in our patients are thus far unresolved. Although normal numbers of T cells were observed by two months post-ABMT, reversed T4:T8 ratio persists for most patients past one year. These phenotypic abnormalities correlated with abnormal T cell responses to mitogens and antigens *in vitro*. Responsiveness of T cells to mitogens was largely absent in all patients within the first two months and was present in $< 50\%$ at 12 to 116 weeks post-ABMT, reflecting a relative decrease in T4⁺ cells. In contrast, responsiveness to either TCGF-CM or allogeneic cells was noted in the majority of patients at ≥ 12 weeks post-ABMT. It is interesting to note that the addition of TCGF-CM to cells stimulated with PHA-LCM or allogeneic cells led to greater proliferation than the proliferation induced by either stimulus alone. This suggests that there may be a relative excess of activated T cells expressing TCGF receptors but that there may be a deficiency of interleukin 2 (IL 2) post-ABMT. A relative deficiency of IL 2 has been previously reported early following allogeneic transplant.⁶³⁻⁶⁵ Since the provision of external IL 2 containing media led to augmentation of T cell proliferation, these T8⁺ cells appear to respond in a normal fashion to TCGF. Again these T cell defects observed *in vitro* do not convert into significant clinical toxicities.

It is of great interest to note that 10% to 15% of PBMCs during the first three weeks post-ABMT express the NKH1 antigen. These cells have both the phenotypic and functional characteristics of NK cells. Large numbers of these cells ($\geq 10\%$ marrow PBMCs) are infused in the graft and may have a selective growth advantage early following ABMT. Previous studies have demonstrated that several NKH1 positive clones isolated from a patient post-allogeneic transplant had demonstrated marked NK activity not only against K562 but also against cryopreserved autologous tumor cells.⁶⁶ The demonstration of *in vitro* cytotoxicity of these NK cells noted post-B1 purging against cryopreserved tumor cells further suggests that these cells may have an *in vivo* role in killing small numbers of residual tumor cells within the host. Depletion of this antitumor effect of NK cells post-ABMT coupled with definition of the factors regulating growth of these cells may offer important insights into the treatment of human tumors.

Our studies suggest that purging autologous bone marrow with anti-B1 MoAb and complement does not inhibit hematologic and immunologic engraftment post-ABMT. More importantly, minimal acute and chronic clinical toxicities are

observed following this treatment modality. The next step in these studies is to improve in vitro ablation by first using multiple antibodies and then comparing complement-mediated lysis to other forms of in vitro ablation. With each of these future studies we must carefully examine not only the in vitro tumor ablation but also the effects of hematologic and immunologic engraftment. Moreover, it is hoped that a better understanding of the growth and regulation of B and T cells will permit us to modulate their growth in vivo and thereby to hasten engraftment.

Association Between Gelatinase Release and Increased Plasma Membrane Expression of the Mo1 Glycoprotein

By Pamela R. Petrequin, Robert F. Todd III, Larry J. Devall, Laurence A. Boxer, and John T. Curnutte III

Mo1, a glycoprotein heterodimer (gp 155,95) that functions as an adhesion promoting molecule and as the C3bi receptor of human myeloid cells, is expressed in increased amounts in the plasma membrane after exposure of polymorphonuclear leukocytes (PMNs) to various stimuli. Previous studies have suggested that secondary granules represent an intracellular pool of Mo1 that, upon degranulation, fuse with the plasma membrane resulting in a tenfold increase in surface expression of Mo1. To determine the intracellular location of Mo1, we monitored Mo1 expression by immunofluorescence and compared it to the release of myeloperoxidase (MPO, a marker for the primary granules), vitamin B₁₂ binding protein (B₁₂BP, secondary granules), and gelatinase (gelatinase-containing organelles) following exposure to various stimuli. Human neutrophils stimulated with 20 mmol/L fluoride for 16

minutes exhibited a twofold increase in Mo1 expression and gelatinase release but no enhanced release of primary or secondary granular contents. In a similar fashion, incubation of cells at 37° C for five minutes with 7.5×10^{-9} to 10^{-6} mol/L N-formyl-methionyl-leucyl-phenylalanine (FMLP) resulted in significant increases in both surface Mo1 expression (three- to fivefold) and gelatinase release (five- to eightfold) without significant release of either MPO or B₁₂BP. In addition, both the fluoride and FMLP experiments demonstrated that Mo1 up-modulation alone is not sufficient to activate superoxide (O₂⁻) production. These data indicate that at least one intracellular storage pool of Mo1 is the gelatinase-containing organelles and that their fusion with the plasma membrane results in increased expression of Mo1 on the cell surface.

THE SURFACE of human myeloid cells contains a glycoprotein, Mo1, a heterodimeric glycoprotein with subunit molecular weights of 155 kD and 94 kD.¹ Mo1, which is equivalent to glycoproteins termed elsewhere as OKM1² and Mac-1,³ serves as the receptor for C3bi-opsonized particles.⁴⁻⁶ In addition, the Mo1 glycoprotein also plays a role in various aspects of cellular adhesion such as adherence, spreading, chemotaxis,⁷ and PMN aggregation.⁸ Upon exposure to various degranulating stimuli, the surface expression of Mo1 increases by up to tenfold, as determined by immunofluorescence,⁹⁻¹¹ enhanced C3bi receptor activity,^{8,12} and PMN aggregation.⁸ This up-regulation of Mo1 appears to be due to the translocation of a large intracellular pool of the glycoprotein to the cell surface.⁹⁻¹³ Evidence for this intracellular location is twofold. First, permeabilized PMNs stained with a fluorescent monoclonal antibody (MoAb) directed against Mo1 show a diffuse granular fluorescence pattern.¹³ Second, subcellular fractionation studies show Mo1 to be present in the fraction enriched for secondary granules as well as in the membrane fraction.^{9,10,13} On the basis of these data it has been postulated that degranulation in PMNs results in the translocation of the secondary granule-associated Mo1 to the plasma membrane, where it is then detected in increased amounts.⁹

While the above data support a secondary granule location for the intracellular pool of Mo1, several lines of experimental evidence suggest that this glycoprotein might be contained in yet another intracellular compartment. First, the surface expression of Mo1 increases under conditions in which primary and secondary granules are not released, such as incubating cells in suspension at 37° C.^{10,13,14} Second, a population of "granules" has recently been described, the gelatinase-containing organelles, that do exhibit this type of lability when incubated at 37° C.¹⁵ Using gelatinase release to monitor these organelles, Dewald et al demonstrated that the gelatinase-containing organelles fuse with the membrane during warming of PMNs as well as during exposure to low (chemotactic) concentrations of FMLP.¹⁵ These experimental conditions caused little, if any, release of primary or secondary granule contents.^{14,15} Third, secondary granules

and gelatinase-containing organelles have nearly identical densities and are therefore difficult to resolve from each other except under fractionation conditions where sedimentation velocity is used.¹⁵ Under the conditions used in the previous reports of Mo1 subcellular localization, the secondary granule fraction was probably contaminated with gelatinase-containing organelles, since the fractionation technique involved density separation.^{9,10} Taken together, these observations raise the possibility that Mo1 may reside in the gelatinase-containing organelles.

To test this possibility, Mo1 surface expression under a variety of conditions was compared to the extracellular release of the contents of primary and secondary granules as well as the gelatinase-containing organelles. Two stimuli were employed, fluoride and FMLP. Fluoride has been previously shown to stimulate the respiratory burst in neutrophils without the concomitant release of markers of either primary granules (myeloperoxidase, β -glucuronidase, lysozyme) or secondary granules (lysozyme, vitamin B₁₂ binding

protein [$B_{12}BP$]).^{16,17} FMLP at low concentrations causes substantial release of gelatinase with minimal release of primary and secondary granule contents.^{15,18} The results reported here indicate that both of these stimuli cause substantial MoI expression and that this is correlated with release of gelatinase but not markers for the primary and secondary granules.

MATERIALS AND METHODS

Chemicals. Sodium fluoride, sodium chloride, and dimethyl sulfoxide (DMSO) were purchased from Fisher Scientific, Fairlawn, NJ. ³H-acetic anhydride and (¹⁴C)-vitamin B_{12} (90 cpm/pg) were purchased from Amersham, Arlington Heights, IL. Ionophore A23187 (Calbiochem, LaJolla, CA), FMLP (Calbiochem), and cytochalasin B (Sigma, St. Louis) were dissolved in DMSO and then added to aqueous solutions with vigorous mixing. All other reagents were purchased from Sigma, St. Louis, unless otherwise stated.

Monoclonal antibodies. Cell surface antigens were monitored by indirect immunofluorescence analysis using monoclonal antibodies (MoAbs) from mouse ascites specific for MoI (IgG-2a subclass)⁵; β -2 microglobulin (IgG-2b subclass), a gift of Dr Lee Nadler, Boston¹⁹; and Ia (IgG-2a subclass).²⁰

Cell preparation. Suspensions of PMNs were prepared from acid citrate dextrose-treated blood by a previously reported procedure.²¹ Except for the step of sedimentation in dextran that was performed at room temperature, cells were kept at 4° C throughout the preparation.

Cell stimulation. For FMLP and A23187 stimulation, cells were diluted to 2×10^6 cells/mL in phosphate buffered saline (PBS)²² (138 mmol/L NaCl, 2.7 mmol/L KCl, 8.1 mmol/L Na_2HPO_4 , 1.5 mmol/L KH_2PO_4 , 0.9 mmol/L $CaCl_2$, 0.5 mmol/L $MgCl_2$, and 7.2 mmol/L glucose, pH 7.4) and prewarmed to 37° C. Cells were incubated for five minutes at 37° C with either FMLP (concentrations ranging from 10^{-6} to 10^{-9} mol/L) or A23187 (10^{-6} mol/L). Cytochalasin B (10 μ mol/L) was added to some control reaction mixtures to induce maximal degranulation. The total concentration of DMSO (the solvent for cytochalasin B and FMLP) never exceeded 2.5 μ L/mL and had no effect on O_2^- production. After incubation, reaction mixtures were transferred to an ice bath and then centrifuged at 600 g for five minutes at 4° C. The cells in the pellets were used for MoI analysis and for determination of total enzyme content, while the supernates were used for measurements of enzyme release. For fluoride stimulation, a modified PBS (PBS') was used so that the final salt concentrations would be physiologic after 20 mmol/L NaF (final concentration) was added.¹⁶ The nonstimulated cells in PBS' received 20 mmol/L NaCl to restore isotonicity. During fluoride stimulation, cells were incubated for up to 17 minutes at 37° C with the samples taken at various times and treated as described above for FMLP stimulated cells.

Measurements of O_2^- production. Superoxide dismutase-inhibitable cytochrome *c* reduction was used to measure O_2^- as previously reported²³ except that the cytochrome *c* concentration was 150 μ mol/L. Cells were prewarmed to 37° C for two minutes prior to stimulation and were used at a final concentration of 2×10^6 cells/mL in a final volume of 1.9 mL. Cytochrome *c* was not limiting as the maximum amount of O_2^- produced was 100.0 ± 6.5 nmol (mean $\pm$ SD), which was less than the 150 nmol available for reduction in the reaction mixture.

Immunofluorescent analysis of membrane antigens. Indirect immunofluorescence of MoI and β -2 microglobulin was measured by flow cytometry as described by Todd et al.⁹ The channel number (log scale) representing the mean fluorescence intensity of 5,000 cells, which had been exposed to either an experimental or a negative control antibody (anti-Ia) and then to a fluorescein-conjugated goat

antimouse immunoglobulin, was determined. Logarithmic channel numbers were converted to linear values,²⁴ and the specific mean fluorescence intensity for cells stained by experimental antibodies was calculated by subtracting the mean channel number of cells exposed to the negative control antibody from that of cells stained by the experimental antibodies. To compare data from one experiment to another, the specific mean fluorescence of experimentally treated cells was compared in each experiment to that resulting from stimulation of neutrophils with 10^{-6} mol/L A23187 in the presence of 10 μ mol/L cytochalasin B for five minutes at 37° C, a value that was defined as the maximum MoI expression.

Granule marker analysis. $B_{12}BP$ was measured by a previously reported modification¹⁴ of the method of Gottlieb et al.²⁵ MPO was measured by the method of Bretz and Baggiolini.²⁶ Lactic dehydrogenase (LDH) was measured as previously described²⁷ and was used as a measure of cellular integrity during stimulation. The extent of release of each of these markers was expressed as the percent of total cellular activity present in the cell supernate following stimulation.

Gelatinase activity was measured by the release of tritium counts from gelatin labeled with ³H-acetic anhydride by the method of Dewald et al.¹⁵ Before samples were assayed they were treated with 3 mmol/L di-isopropylphosphorofluoridate (DFP) to inhibit serine proteases.¹⁵ Gelatinase-dependent tritium release was defined as the difference between the total counts released by the extracellular medium samples and the counts released in the presence of buffer alone. Gelatin breakdown was found to be linear with substrate concentration from 20 to 100 μ g/mL, time from 1.5 to 3.0 hours, and cell concentration from 5×10^5 to 5×10^6 cells/mL. In a typical assay containing substrate at a concentration of 20 μ g/mL (total 42,000 cpm) and supernates from cell suspensions (2×10^6 cells/mL) incubated under various conditions, the following counts were released from gelatin: unstimulated cells at 4° C for five minutes, 90 cpm/ 10^5 cells; 37° C for five minutes without stimulus, 360 cpm/ 10^5 cells; and 37° C for five minutes with 10^{-6} mol/L A23187 and 10 μ mol/L cytochalasin B, 1030 cpm/ 10^5 cells. The presence of an inhibitor in the cytosol resulted in an inability to measure accurately the total activity in the intact cell.²⁸ Therefore, gelatinase release was expressed not as percent release as with the other markers but instead as the absolute amount of substrate degraded by the extracellular fluid derived from the incubation of a fixed number of cells. Maximum release was defined as the gelatinase activity present in the extracellular medium following stimulation of neutrophils with 10^{-6} mol/L A23187 and 10 μ mol/L cytochalasin B for five minutes.

RESULTS

In Fig 1 the effects of temperature and fluoride on MoI surface expression and gelatinase release are shown. The data are expressed as the percent of maximum response defined as that observed in the presence of A23187 and cytochalasin B. It can be seen that warming PMNs from 4° C to 37° C resulted in a significant increase in both gelatinase release (1.8-fold) and surface MoI expression (1.8-fold) without concomitant release of MPO or $B_{12}BP$, markers for the primary and secondary granules, respectively. Subsequent stimulation of the prewarmed PMNs by fluoride caused a further increase in gelatinase release (1.85-fold) and in MoI expression (2.0-fold) above the 37° C control, again without release of primary or secondary granules. Control experiments showed no release of LDH (data not shown), indicating cellular integrity. In addition, $B_{12}BP$ and MPO could readily be detected by our assay techniques when cells were exposed to A23187 and cytochal-

Fig 1. Fluoride stimulation of Mo1 expression and granule marker release. PMNs were incubated in 20 mmol/L fluoride and PBS' for 15 minutes (▨) before Mo1 expression and enzyme release were measured. NaCl was added to unstimulated cells at 4° C (■) and at 37° C (▩) to bring the PBS' to isotonicity. The brackets indicate the SEM for six experiments. The maximum response was defined as the amount of activity measured after cells were incubated with 10^{-6} mol/L A23187 and 10 μ mol/L cytochalasin B for five minutes. Average maximum values ($\pm$ SEM) are as follows: gelatinase, 1028 ± 295 cpm/ 10^6 cells; Mo1, 130 ± 29 mean fluorescence units/cell (arbitrary units); B₁₂BP release, $39\% \pm 9.2\%$ of total cell B₁₂BP; and MPO release, $53.5\% \pm 4.5\%$ of total cell MPO. * $P < 0.006$ by paired t test for 4° C v 37° C and 37° C v F1-. ‡Difference is not significant for 37° C v F1-.

asin B, indicating that failure to correlate fluoride-induced Mo1 expression with granule release was not due to adherence of the granule proteins to the cell surface. The levels of MPO and B₁₂BP released were substantial and not statistically different from each other.

Experiments were then performed to determine the time courses of Mo1 expression and gelatinase release following fluoride stimulation. In addition, O₂⁻ production was measured simultaneously to see if its activation was correlated temporally with either gelatinase release or Mo1 up-modulation. As shown in Fig 2, both Mo1 surface expression and gelatinase release rise concomitantly, beginning as early as three minutes after the addition of fluoride and continuing through the entire 16-minute incubation. In contrast, there was no significant release of B₁₂BP and MPO under these conditions. Superoxide production did not correlate with either Mo1 expression or gelatinase release, as it began substantially later after its characteristic nine-minute lag period.^{16,17} Thus the appearance of Mo1 on the cell surface and the release of gelatinase were closely correlated in time and appeared to occur independently of O₂⁻ production and the release of primary and secondary granules.

Since Dewald et al have previously reported that chemotactic concentrations of FMLP (10^{-9} to 10^{-8} mol/L) cause significant gelatinase release with minimal release of B₁₂BP and MPO,¹⁵ the effect of FMLP on Mo1 surface expression was next determined. Figure 3 shows the effect of various concentrations of FMLP on the expression of Mo1 and the release of gelatinase. Increases in cell surface Mo1 and gelatinase release occurred in parallel at all concentrations of the stimulus except at the lowest concentration of FMLP where the level of sensitivity of the gelatinase assay was limiting and little or no gelatinase activity could be detected.

Fig 2. Time course of Mo1 expression, superoxide production, and release of gelatinase, B₁₂BP, and MPO following fluoride stimulation. Mo1 expression (■), gelatinase release (●), O₂⁻ production (▲), B₁₂BP release (○), and MPO release (□), were measured at various times after fluoride (20 mmol/L) had been added to 2×10^6 PMNs/mL at 0 minutes. The data from four experiments are expressed as percentage of maximum response (cells exposed to 10^{-6} mol/L A23187 and 10 μ mol/L cytochalasin B for five minutes) $\pm$ SEM. The values for the unstimulated control did not change during the course of the incubation and were subtracted from the fluoride measurements. The maximum responses ($\pm$ SEM) were as follows: for Mo1, 98 ± 43 mean fluorescence units/cell; for gelatinase release, $1,035 \pm 316$ cpm/ 10^6 cells; for B₁₂BP release $47\% \pm 6\%$ of total cell activity; for MPO release $48\% \pm 9\%$ of total cell activity; and for O₂⁻ production, 108 ± 10 nmol/min/ 1×10^7 cells (initial velocity).

Fig 3. The effect of FMLP concentration on Mo1 expression, O₂⁻ production, and release of gelatinase, B₁₂BP, and MPO. Separate aliquots of PMNs at 2×10^6 cells/mL were exposed to different concentrations of FMLP (10^{-9} to 10^{-8} mol/L) for five minutes at 37° C and assayed for Mo1 expression, O₂⁻ production, and enzyme release as described in "Methods." Activity in unstimulated cells incubated at 37° C for five minutes was subtracted from the values obtained with stimulated cells. The data from four experiments are expressed as the mean $\pm$ SEM for: Mo1 expression (■), in arbitrary mean fluorescence units; gelatinase release (●), in cpm/ 10^6 cells; O₂⁻ production (▲), in nmol/min/ 10^7 cells; and for granule marker release [B₁₂BP (○) and MPO (□)] in percentage of total cell activity.

At 10^{-8} mol/L FMLP, Mol expression and gelatinase release were nearly maximal, while there was insignificant release of both B_{12} BP and MPO. Only at higher concentrations of FMLP (10^{-7} mol/L) was the release of primary or secondary granule contents observed. In all cases minimal LDH was released (data not shown). As with MPO and B_{12} BP release, higher concentrations of FMLP (greater than 2.5×10^{-8} mol/L) were required to activate O_2^- production. Thus increases in the expression of Mol on the cell surface and the release of gelatinase were closely correlated at all concentrations of FMLP and could be dissociated from O_2^- production and from release of primary and secondary granules.

DISCUSSION

Our data suggest that human PMNs exhibit at least three levels of activation with respect to Mol expression and exocytosis. Upon intense stimulation (eg, with A23187 and cytochalasin B), substantial amounts of Mol are expressed on the cell surface while secondary granules, primary granules, and gelatinase-containing organelles all release their contents into the extracellular medium. At the other extreme, in which the cells are in their basal or unstimulated state (defined experimentally as PMNs maintained at 4°C), only 10% as much Mol is expressed and little, if any, exocytosis occurs. An intermediate state of activation can also be identified, perhaps part of a continuum of the activation process, in which approximately 50% of the maximal Mol is expressed on the cell surface and in which only the gelatinase-containing organelles undergo appreciable exocytosis. Stimuli such as fluoride and FMLP (at low concentrations) cause this intermediate level of activation and provide an experimental system for correlating Mol expression with exocytosis of gelatinase-containing organelles.

We provide here strong evidence that in the basal and intermediate levels of activation, Mol expression is not related to the release of primary or secondary granules. When maintained at 4°C , neutrophils express Mol without any ongoing exocytosis, indicating that there is a certain amount of Mol already present in the plasma membrane. With fluoride as a stimulus, Mol expression increases to approximately 50% of its maximum without any net increase in the release of B_{12} BP or MPO (Figs 1 and 2). These data are consistent with previous reports demonstrating absence of primary and secondary granule release in response to fluoride.^{16,17} Similar results were obtained with FMLP at concentrations below 10^{-8} mol/L where more than 50% of the Mol is expressed with less than 10% release of the primary and secondary granules.¹⁵ Taken together these data indicate that the primary and secondary granules do not contain the intracellular reserves of Mol that are expressed in the intermediate state(s) of PMN activation.

If this labile reserve pool of Mol is not located in the primary and secondary granules, where is it located? One possibility would be cryptic sites within the plasma membrane that are exposed following stimulation. This, however, does not appear to be the case based on two findings in

previous reports.^{9,13} The first observation was that the Mol antigen was found to be located predominantly in a secondary granule-containing fraction and present only in small amounts in the plasma membrane fraction.^{9,13} The second was that immunofluorescent staining of PMNs with the Mol antibody showed a granular intracellular staining pattern.¹³ Based on these studies it would appear that the Mol reserve pool is located within the cell and not in the membrane. Two observations in the literature suggest that the gelatinase-containing organelles may be one major intracellular site. First, gelatinase-containing organelles have a density nearly identical to that of the secondary granules and would therefore co-purify on density gradients with the secondary granule fraction that reacts with Mol.^{9,10,13,15} Second, the gelatinase-containing organelles are quite labile and readily fuse with the plasma membrane upon warming or gentle stimulation, properties that are strikingly similar to the Mol expression seen in the intermediate stages of activation. We now provide data showing a strong correlation between Mol expression and the fusion of gelatinase-containing organelles with the plasma membrane. With fluoride, the time course of Mol expression and gelatinase release closely parallel each other, while in the FMLP experiments, the dose-response curves for Mol and gelatinase are strikingly similar. In quantitative terms, fluoride causes the release of 60% of the releasable gelatinase, a value that agrees closely with the 50% maximal Mol expression induced by this stimulus. A similar quantitative relationship is observed with FMLP. Thus the intermediate level of Mol expression occurs in the absence of primary and secondary granule release and strongly correlates with exocytosis of the gelatinase-containing organelles.

Since approximately 50% of the maximal Mol is expressed under conditions where roughly 50% of the maximal gelatinase is released, it is tempting to speculate that the remaining Mol is also located in the gelatinase-containing organelles. Because of the lack of specificity of the gelatinase assay, however, the possibility that some Mol is located in the secondary granules cannot be excluded. The substrate employed in the gelatinase assay (derived from type I collagen) can be degraded by neutrophil collagenase²⁹ present in the secondary granules³⁰ as well as by elastase in the primary granules.³¹ Experimental conditions which result in maximum Mol expression (A23187 + cytochalasin B) also cause the release of substantial amounts of primary and secondary granule contents.¹² The collagenase and elastase thus released contribute to the total gelatinolytic activity and make it difficult to determine the contribution of the gelatinase-containing organelles. Because of these technical limitations, the most that can be concluded from the data is that at least 50% of the Mol that is eventually expressed is contained in the gelatinase-containing organelles. Whether the remaining 50% is localized to the same organelles or to the specific granules can only be determined by direct measurements of Mol in subcellular fractions in which specific granules are resolved from the gelatinase-containing organelles. This, however, requires the sophisticated technology of rate zonal sedimentation.

The possibility that at least some of the intracellular pool

of Mo1 is contained in the specific granules is supported by studies on a patient with specific granule deficiency.¹³ Mo1 expression in these experiments was determined by measuring the number of C3bi receptors on the cell surface. PMNs from the patient exhibited abnormal up-regulation of C3bi in response to stimulation, suggesting a specific granule location for at least part of the Mo1. Whether the gelatinase-containing organelles in this patient were also abnormal, however, was not reported.

Mo1 expression does not appear to be sufficient to activate O_2^- generation. In both the fluoride and FMLP experiments, substantial amounts of Mo1 were expressed without concomitant O_2^- generation. We cannot exclude the possibility, however, that Mo1 might still be necessary for respiratory burst activation, since we have not observed O_2^- production in the absence of Mo1 up-regulation.

The localization of at least 50% of the intracellular Mo1 in the labile gelatinase-containing organelles may have physio-

logic relevance. During chemotaxis when PMNs are exposed to low concentrations of chemotactic agents like FMLP, gelatinase-containing organelles will fuse with the plasma membrane and cause increases in both the amount of Mo1 expressed on the cell surface and the amount of gelatinase in the extracellular medium. This increase in Mo1 would enhance PMN attachment to surfaces, a necessary step required for efficient chemotaxis of PMNs through tissues. The gelatinase could serve to partially degrade connective tissue that might impede the mobility of the PMNs. Finally, this early deployment of Mo1 would also eventually facilitate recognition and ingestion of microbes opsonized with C3bi, since it also functions as the C3bi receptor.

ACKNOWLEDGMENT

The authors thank David A. Brott for his help in measuring Mo1 levels by flow cytometry.

Gene Transfer to Primary Normal and Malignant Human Hemopoietic Progenitors Using Recombinant Retroviruses

By Donna E. Hogge and R. Keith Humphries

To study the feasibility of using retroviruses for gene transfer into human hemopoietic cells, various cell types were exposed to virus carrying the gene for neomycin resistance (*neo'*). In preliminary studies using K562 cells as targets, we found that high viral titer and co-cultivation with viral producer cells rather than incubation in medium exposed to viral producer cells were important variables for achieving high frequencies of G418 resistant (G418^r) colonies. The maximum frequency of G418^r K562 colonies after co-cultivation with cells producing a *neo'* virus titer of 4×10^6 cfu/mL was 60%. When primary human progenitors from normal marrow, fetal liver, or chronic myelogenous leukemia blood were exposed to high titer

viral stocks, both with and without helper virus, under conditions optimized for K562 cells, maximum frequencies of G418^r colonies were 3% to 16% for granulocyte macrophage progenitors and 2% to 6% for primitive erythroid progenitors. The presence of the *neo'* gene in both G418^r K562 and primary hemopoietic colonies was verified by Southern blot. Expression of the *neo'* gene was shown by RNA spot blot. These data demonstrate efficient transfer and expression of the *neo'* gene in both K562 cells and primary human hemopoietic cells from normal and leukemic individuals.

THE DELIVERY of exogenous genetic material into various target cells is important for many experimental and clinical goals. Recombinant retroviruses provide an attractive vehicle for gene transfer for a number of reasons. These include the high efficiency with which they are able to enter cells and integrate into host DNA, their wide target cell range, and their lack of toxicity.¹ Mammalian bone marrow is a convenient source of primitive cells with high proliferative and self-renewal capacity on which to test the feasibility of using a gene transfer technique to primary cells. A number of workers have already shown that it is possible to introduce a variety of foreign genes into the bone marrow stem cells of mice using recombinant retroviruses.²⁻⁷ These authors have shown a high efficiency of gene transfer, and the transferred gene has remained stably integrated through serial marrow transplants. Although some expression of the transferred genes has been demonstrated, difficulties in obtaining satisfactory levels of the products of certain genes such as human adenosine deaminase have been encountered.⁷ In addition, the long-term stability of gene expression has been questioned.⁵ Nevertheless, it is clear that retroviruses are capable of delivering functional genes into murine hemopoietic progenitors.

Retroviruses have also been used for gene transfer to human cells, although the available data are less extensive than for murine targets.⁷⁻¹² The enzyme deficiency in hypoxanthine phosphoribosyl transferase (HPRT) negative human fibroblasts and B lymphoblasts has been corrected by infection with recombinant virus containing the HPRT gene.^{8,9} Similar results have been reported for experiments in which a virus containing the human adenosine deaminase (ADA) gene was used to infect human ADA-deficient B lymphocytes.⁷ Some data exist for cells of the hemopoietic system from experiments in which long-term human marrow cultures were infected with virus containing oncogenes or the human HPRT gene.^{10,11} Viral replication in the hemopoietic cells in these cultures was documented, but the extent to which the gene of interest had been successfully transferred and expressed by primitive blood cell progenitors was not studied. Recently more direct quantitative data have been published by Hock and Miller¹² demonstrating retroviral-mediated gene transfer to primary human marrow progeni-

tors with recombinant viruses carrying the *neo'* or the DHFR* gene.

The present study was undertaken to investigate and identify variables that may influence the frequency of successful gene transfer to human hemopoietic progenitors. A number of the available viral packaging lines and retroviral vectors have been evaluated using a spectrum of target cell types including an established cell line as well as fresh progenitors of both normal and leukemic origin.

MATERIALS AND METHODS

Cells and culture conditions. Cell lines were cultured in Dulbecco's modified Eagle medium with high glucose (4.5 g/L) and 10% heat-inactivated calf serum (for ψ AM or ψ 2 cells) or 10% fetal calf serum for all other cell types in 5% CO₂ atmosphere at 37 °C. The amphotropic retrovirus packaging lines, ψ AM, PA12 and PA317, and the ecotropic packaging line, ψ 2, have been previously described.¹³⁻¹⁶

Primary human cells were obtained either from consenting adults (CML peripheral blood or normal bone marrow) or from second trimester abortions (fetal liver cells) after approval from the Clinical Screening Committee for Research Involving Human Subjects of the University of British Columbia. Blood and bone marrow cells were passed over a percoll density gradient (density 1.063) and light

density cells collected and used in subsequent experiments. Fetal liver was minced with scissors and incubated for three hours at 37 °C in α medium with 20% fetal calf serum and collagenase 1 mg/mL (Sigma, St. Louis). The cells were then passed through a succession of needles of decreasing gauge, washed, and used for the experiments described.

Primary human cells were grown in α medium supplemented with 20% fetal calf serum and 10% agar-stimulated leukocyte-conditioned medium while in suspension culture and in methylcellulose assays as previously described¹⁷ for assessment for hemopoietic progenitors.

Virus production and assay. The general strategy for generating high-titer retroviral-producer cell lines was as outlined by Miller et al.¹⁸ The retrovirus packaging line, ψ 2, was transfected with viral plasmid DNA (pZipNeo or pN2).^{6,19} These plasmids are both MoMuLV-based vectors that contain the gene for neomycin phosphotransferase (neo^r). After 48 hours the medium from the transfected ψ 2 cells that contained neo^r virus (v-neo^r) was removed, and aliquots were used to infect the amphotropic packaging lines, ψ AM, PA12, or PA317. After 48 hours amphotropic v-neo^r-producing clones were selected in medium containing the neomycin analogue G418 at 1 mg/mL (Gibco Laboratories, Chagrin Falls, OH). G418 was dissolved in distilled water and added to growth medium to achieve the desired final concentration in total mg/mL (the effective drug concentration was approximately 50% of that value for the two lots of G418 used). Colonies were isolated by cloning rings, expanded, and examined for v-neo^r titer on 3T3 cells and for amphotropic helper virus using the S + L⁻ assay.¹⁵

Viral infection. The K562 human leukemic cell line or primary cells were infected with v-neo^r by either co-cultivation with amphotropic viral producer cells that had received 1,500 R irradiation or incubation in medium previously exposed to virus-producing cells for various periods of time. After the infection period they were maintained in suspension culture for 24 to 48 hours before plating in methylcellulose assay with or without G418. Control cultures that were not exposed to virus were grown in suspension culture and plated with or without G418 at the same time as the infected cells. All infections and control suspension cultures were done with polybrene, 8 μ g/mL. Colonies were scored after plating in methylcellulose on days 5 to 7 for K562 and days 10 to 14 for granulocyte macrophage colonies (from CFU-GM) and days 18 to 21 for large erythroid colonies (from BFU-E) for primary progenitor assays. Colonies were not scored unless they contained at least 30 cells and, in the case of BFU-E, had at least three clusters and were clearly hemoglobinized.

The infectious center assay was done by picking individual G418 resistant (G418^r) granulocyte-macrophage colonies from methylcellulose assay and placing the dispersed cells from one colony in a 2 cm² tissue culture well containing 10⁴ NIH-3T3 cells in medium with 8 μ g/mL polybrene. After overnight incubation the medium was replaced with fresh medium containing G418 1 mg/mL. Seven days later the assay was scored for the presence of G418^r 3T3 cells.

Cell and viral manipulations and cultures were performed under level C containment following Medical Research Council of Canada guidelines for handling retroviruses and human samples.

DNA and RNA studies. High molecular weight DNA was harvested from expanded clones of K562 cells and pooled hemopoietic colonies by proteinase K digestion followed by phenol and chloroform extractions. Southern blotting of K562 and primary hemopoietic colony DNA to nitrocellulose filters was performed by standard methods.²⁰

Total cellular RNA was harvested by the method of Meinkoth and Wahl²¹ from K562 or from primary hemopoietic colonies that had been individually plucked and pooled from methylcellulose

assays. The RNA was diluted to various concentrations and applied to nitrocellulose filters using a spot blot manifold according to established methods (Schleicher and Schuell, Keene, NH).

To detect neo^r sequences, a 2.3 kb neo^r-specific Bam HI, Hind III fragment isolated from RSV-neo plasmid DNA was ³²P-labeled by nick translation kit (Bethesda Research Laboratories, Gaithersburg, MD) for use as a probe. Filters were prehybridized, hybridized, washed, and autoradiographed using standard techniques.²⁰

RESULTS

Viral producer cells. Many attempts were made to obtain the highest possible v-neo^r titer from various combinations of packaging lines and either the ZipNeo or the N2 vector. For the combination of ψ AM cells and pZipNeo, the highest titer of helper-free virus obtained after screening 61 clones was 2×10^4 CFU/mL. With PA12 and pZipNeo, several of the 21 clones studied produced approximately 10⁵ CFU/mL, but these were found to produce helper virus as well. With the combination of PA12 and the N2 vector, higher titers of v-neo^r (4×10^6 CFU/mL) were obtained, but these also contained helper virus. The highest titers of helper-free v-neo^r (5×10^5 CFU/mL) were obtained from the PA317 packaging cell line containing the N2 proviral DNA.

K562 experiments. To optimize conditions for high-frequency retroviral infection of human hemopoietic progenitors, we used K562 cells as a convenient model for experiments in which a number of variables were explored. Initially the best ratio of target K562 cells to irradiated viral producer cells was studied over a range of 10⁴:1 to 1:10. The transformation of K562 to G418^r increased in frequency as the proportion of v-neo^r producer cells increased up to a cell ratio of 1:1 and then plateaued with higher numbers of producer cells. A total of 10⁵ K562 cells were then incubated for two hours with 3 mL of medium exposed to v-neo^r producing cells, either undiluted or diluted to concentrations as low as 1:10³. There was a direct correlation between the concentration of v-neo^r-containing medium and the frequency of G418^r K562 cells for medium from all the viral producer lines tested. For the highest titer virus (4×10^6 CFU/mL) the frequency plateaued above concentrations of 1:10.

Figure 1 shows the frequency of G418^r K562 cells obtained by infection with undiluted v-neo^r-containing medium or co-cultivation with confluent cells of various types. The cell lines selected were those producing the highest v-neo^r titer for the various packaging line/neo^r plasmid combinations. At viral titers $\leq 10^5$ CFU/mL the maximum frequency of G418^r K562 cells was approximately 2% after co-cultivation with producer cells. Frequencies obtained after infection with medium exposed to the same cell lines was at least fourfold lower than that obtained by co-cultivation. At the highest titer, 4×10^6 CFU/mL, the difference in efficiency between co-cultivation and cell-free medium disappeared. The highest frequencies of G418^r K562 colonies were obtained with the PA12/N2 producer cells, approximately 60% for both co-cultivation with producer cells and incubation with medium.

A number of other variables that were investigated did not

Fig 1. G418^r K562 colonies (% of colonies grown without G418) after infection of 10⁵ cells for two hours with v-neo^r from 3 mL undiluted medium or 24 hours exposure to a 60-mm dish of confluent, irradiated viral producer cells of various types. Each bar represents the results of a single experiment. Similar results were obtained in a second set of experiments. The G418 concentration of 1 mg/mL completely inhibited colony growth of uninfected cells. □, medium; ▨, co-cultivation.

appear to affect the frequency of K562 cell transformation to G418^r. These included extending the duration of co-cultivation from six to 48 hours or extending the duration of exposure to medium from producer cell lines from two to 48 hours.

The neo^r gene was demonstrated in G418^r K562 cell DNA by expanding individual colonies in liquid culture and extracting cellular DNA for Southern blots. Figure 2A demonstrates the 4kb neo^r-specific XbaI fragment found in four G418^r K562 colonies but not found in control K562 DNA. Figure 2B shows DNA from the same four G418^r K562 colonies and two uninfected control K562 colonies cut with enzymes that cut only once within the neo^r proviral DNA. The neo^r-specific fragments demonstrated in the G418^r colonies are single and unique to each colony, indicating one random site of integration for the provirus in the cellular DNA.

Infections of primary hemopoietic progenitors. A total of four normal marrow, six fetal liver, and six CML blood samples were infected with v-neo^r from a variety of packaging cell line/neo^r plasmid combinations. The infection procedure did not appear to be toxic to the target cells as shown by a lack of any effect on cell recovery or plating efficiency. (Values for infected cells were 80% to 100% of control values.) A G418 concentration of 2 mg/mL (effective drug concentration 1 mg/mL) completely inhibited all colony

Fig 2. Southern blots of total cellular DNA hybridized with a ³²P-labeled neo^r-specific Bam H1-Hind III fragment from pRSV-neo. (A) K562 DNA from cloned G418^r cells infected with ψAM/ZipNeo viral stocks (lanes 1 to 4) or uninfected (lane 5) and digested with XbaI. → 4kb neo^r-specific fragment in infected cells. (B) DNA from the same G418^r K562 clones as in (A) (lanes 1 to 4 and 7 to 10) and uninfected clones (lanes 5, 6, 11, 12) digested with Bam HI (lanes 1 to 6), or EcoRI (lanes 7 to 12). These enzymes cut once within proviral DNA and once within cellular DNA to generate a single neo^r specific fragment of unique size in each of the G418^r clones. (C) DNA from pooled primary hemopoietic colonies either infected with PA12/N2 viral stocks (lanes 2, 3, 5) or uninfected (lanes 1, 6, 7) and digested with EcoRI. The expected 1.5 kb neo^r specific fragment is seen in lane 2 (cells infected with viral supernatant but not selected in G418), lane 3 (G418^r cells after infection with supernatant), and lane 5 (cells infected by co-cultivation with producer cells but not selected in G418). Lane 4 shows no neo^r specific hybridization from cells exposed to supernatant from PA317/N2 producer cells but not selected in G418.

growth in assays of uninfected primary progenitors. No difference in G418 sensitivity between the various target cell sources or between progenitors of different lineages (ie, BFU-E and CFU-GM) could be demonstrated.

Figure 3A shows the frequency of G418^r CFU-GM seen after infection by v-neo^r producer cells at various viral titers. Each point represents a different experiment combining target cells of a certain type with a specific viral producer cell line. Although there was a correlation between viral titer and frequency of G418^r, considerable variation in transformation efficiency at any given titer was also found; for example, from 2.4% to 15.7% G418^r CFU-GM at a titer of 4 × 10⁶ CFU/mL. There was also a low (0.045% to 0.4%) but reproducible incidence of G418^r colonies after infection with cells producing viral titers as low as 10³ CFU/mL.

Figure 3B shows similar data for BFU-E. Infections with cells producing a v-neo^r titer of 1 × 10³ CFU/mL yielded a

Fig 3. Frequency (%) of G418^r primary hemopoietic colonies (G418^r colonies/total colonies without G418 × 100) after 24-hour exposure of 5×10^6 cells to a 60-mm dish of irradiated, confluent v-neo⁺ producer cell lines at various viral titers. ●, normal bone marrow; ○, CML blood; ▲, fetal liver. (A) Granulocyte, macrophage colonies; CFU-GM. (B) Large erythroid colonies; BFU-E.

frequency of large G418^r erythroid colonies of less than 1%, while frequencies up to 5.6% were seen after infections done with cell lines producing higher titers. However, the correlation of G418^r frequency with titer was less clear, and the variation in G418^r frequency at any given titer was similar to that seen for CFU-GM. From these data (Figs 3A and B) it appears that BFU-E may be less readily transformed by v-neo⁺ than CFU-GM. Although this may be true, it is possible that the apparent difference is the result of experimental variables that particularly affect erythroid colony growth. For example, it was found that in general G418^r erythroid colonies were not as large or as red as those obtained from infected BFU-E plated in the absence of G418. It is possible that impurities in the G418 affect the growth of erythroid colonies containing the neo^r gene. Alternatively, the neo^r gene may be expressed at a lower level in erythroid cells as they differentiate. Therefore it is likely that the frequencies recorded here for G418^r BFU-E represent minimum estimates of successful gene transfer.

The maximum frequencies of G418^r progenitors from these experiments are summarized in Table 1. The highest frequency was usually obtained after infection with the cell line producing the highest viral titer, PA12/N2 cells producing v-neo⁺ at 4×10^6 CFU/mL, in addition to helper virus.

The ability of medium exposed to v-neo⁺-producing cells,

as compared to co-cultivation with producer cells of various types, to transform primary progenitors to G418^r is compared in Fig 4. At a titer of 6×10^3 CFU/mL produced by ψ AM/ZipNeo cells, v-neo⁺-containing medium was unable to produce a significant incidence of G418^r colonies while co-cultivation yielded a frequency of approximately 0.1%. At titers of 5×10^5 or 4×10^6 CFU/mL, medium with virus was effective at transforming both BFU-E and CFU-GM. However, the frequency was still two- to 50-fold higher using co-cultivation. Nevertheless, the frequency of G418^r colonies was higher after infection with medium at high titers (10.6% for CFU-GM at 4×10^6 CFU/mL) than with co-cultivation at low titers (0.13% CFU-GM at 6×10^3 CFU/mL).

The frequencies of transformation for primary progenitors were not as high as those obtained for K562 cells. To try to increase the efficiency, target cells were allowed to remain on viral producer cells for as long as seven days without any increase in the efficiency of transformation.

The ability of G418^r CFU-GM that had been infected with helper-containing v-neo⁺ to infect 3T3 cells was tested by infectious center assay. In two experiments, five of 22 and 24 of 24 individual CFU-GM tested transformed 3T3 cells to G418 resistance. The production of G418^r 3T3 cells in this assay requires that the infecting cells be producing v-neo⁺. To do so they themselves must have been infected by both v-neo⁺

Table 1. Maximum Frequency of G418^r 1⁰ Hemopoietic Colonies After Co-cultivation With Various v-neo⁺ Producer Cells

* + Helper virus.

†Control = Cells from the same sample plated in methylcellulose $\pm$ G418 without exposure to v-neo⁺ producer cells.

Fig 4. Frequency (%) of G418^r primary hemopoietic progenitors (G418^r colonies/total colonies without G418 × 100) after infection of 5×10^6 cells by v-neo^r from a 60-mm dish of irradiated confluent producer cells for 24 hours or 5 mL undiluted medium of various types for two hours. Each bar represents the results of one experiment. For each viral titer the target cells were from the same individual for all conditions studied. At titers of 5×10^5 and 4×10^6 CFU/mL, the same CML blood cells were used. CML cells were also used at 6×10^3 CFU/mL and fetal liver cells at 3×10^4 CFU/mL. Similar results were obtained in a second set of experiments. BFU-E exposed to v-neo^r medium, □; BFU-E exposed to confluent producer cells, ▤; CFU-GM exposed to v-neo^r medium, □; CFU-GM exposed to confluent producer cells, ▤.

and helper virus, which may occur relatively infrequently.¹² This would account for less than 100% of G418^r CFU-GM being positive in the infectious center assay.

Figure 2C is a Southern blot of DNA harvested from pooled hemopoietic colonies grown from CML blood cells that were either uninfected or exposed to viral stocks containing v-neo^r. After digestion with EcoRI, the neo^r-specific probe identified the expected 1.5 kb neo^r-specific fragment in G418^r cells (lane 3). A less intense signal is seen in lane 2 where the same cells were exposed to medium containing v-neo^r but not selected in G418, indicating that some of the cells did not contain the neo^r gene (8% of the CFU-GM in this sample were G418^r). In lane 5 the DNA from cells exposed to viral producer cells but not selected in G418 shows a strong signal. In colony assays 15.7% of the CFU-GM in this sample were G418^r. The strength of the hybridization signal in lane 5 as compared to lane 3, where an equivalent amount of DNA was hybridized, indicates that at least 15.7% of the cells in this sample contained the neo^r gene. DNA from cells from the same sample that were not exposed to virus in lanes 1, 6, and 7 show no signal.

Expression of the neo^r gene by v-neo^r infected, pooled primary progenitors or K562 cells was shown by RNA spot blot (Fig 5). Total cellular RNA was hybridized with a neo^r-specific probe. Uninfected, control cells show no evidence of neo^r hybridization, while the same number of infected cells show a strong signal. The signal is strongest for cells that were selected in G418 (lanes b, CFU-GM and all infected K562 cells) but is also seen in cells that were infected but not selected (lanes a, CFU-GM).

Fig 5. RNA spot blot of total cellular RNA from pooled CML granulocyte-macrophage colonies or K562 cells hybridized with a ³²P-labeled neo^r specific Bam HI-Hind III fragment from pRSV. Control cells were not exposed to v-neo^r or G418. Cells exposed to either PA12/N2 or PA317/N2 v-neo^r producer cells were either selected in G418 (b) or unselected (a) in the case of CFU-GM. Insufficient cells were available to allow samples for the PA317/N2, 4×10^5 cells column. Therefore, these two spots are blank. All infected K562 cells were selected in G418. pZipNeo DNA serves as a positive control in the top lane (2.0 and 0.5 pg DNA from left to right).

DISCUSSION

These data demonstrate efficient transfer and expression of the neo^r gene to both the K562 human leukemic cell line and a variety of normal and malignant primary human hemopoietic progenitors using recombinant retroviruses.

A number of variables were investigated to try to achieve the highest possible efficiencies of gene transfer. Co-cultivation with viral producer cells rather than infection with medium exposed to viral producer cells and use of high titer virus were both identified as important parameters, but viral titer clearly had the greatest influence on the frequency of transformation to G418 resistance. Considerable effort was

devoted to studying viral producer cells generated by various packaging line/*neo'*-containing plasmid combinations. The choice of these variables had a major impact on the titer of both v-*neo'* and helper virus. We were unable to generate high titer v-*neo'* from the PA12 packaging line that was not associated with helper virus. The use of the N2 vector rather than ZipNeo raised the v-*neo'* titer but did not eliminate the problem of helper virus. Although the PA12 line has been constructed to generate helper-free recombinant virus, it appears that with the vectors used in this study sufficient genetic recombination occurs between the defective packaging and recombinant *neo'* viral sequences to frequently generate significant helper virus titers. Helper-free v-*neo'* generated by the ψ AM packaging line containing pZipNeo DNA was always of relatively low titer ($<10^5$ CFU/mL). The newer generation of retroviral packaging lines, such as the PA317 developed by Miller and Buttimore,¹⁶ may solve the problem of obtaining high-titer recombinant virus without associated helper.

Although both ZipNeo and N2 contain the same *neo'* gene under the control of the promoter in a Moloney leukemia virus LTR, the two vectors are not identical in structure.^{6,19} Although the differences appear subtle, they seem to affect the viral titers obtained from producer cells and might also cause different levels of expression of the transferred foreign gene in infected hemopoietic cells. For this reason we elected to test virus derived from both the N2 and ZipNeo vectors on our target cells. Although our data are not definitive, some of our results (eg. Fig 1 where K562 were the target cells and a fivefold increase in viral titer led to a 20-fold increase in frequency of G418^r colonies) may be explained if *neo'* was expressed more efficiently in cells infected with virus derived from N2 rather than ZipNeo.

In experiments done with helper-free virus from a producer line derived from PA317 cells and the N2 plasmid, we were successful in demonstrating gene transfer at levels only slightly lower than those achieved with helper containing virus of significantly higher v-*neo'* titer. No obvious effect of helper virus on the frequency of gene transfer was detected.

In addition to normal bone marrow we evaluated two alternative sources of primary human progenitors for retroviral infections. These were fetal liver and CML blood. In both cases a high proportion of the primitive progenitors in these tissues are in the active part of the cell cycle as compared to their counterparts in normal marrow, which are largely quiescent.²² Cell cycling status has been suggested as an important variable affecting the success of retroviral infection and integration into host DNA.²³ Although some of our highest frequencies of G418^r colonies were seen in the CML blood cultures, there was sufficient variability from experiment to experiment that no overall difference was evident. However, there was clearly no dramatic improvement in the frequency of G418^r progenitors in experiments using either of the primary human targets that were presumably cycling optimally.

There are many possible reasons for the variability in the frequency of successful gene transfer and expression in primary progenitors, as illustrated in Fig 3. Although the viral titer from our v-*neo'* producer cell lines was quite stable

over long periods of time, some differences did occur. For example, after the producer cells reach confluence the viral titer begins to drop significantly. Similarly, the ability of target cells not only to become infected but to integrate and express the viral genome is probably affected by a number of factors, including their level of differentiation, cell cycle status, and perhaps subtle metabolic factors that may be altered by the unavoidable day-to-day changes in complex culture conditions. Although care was taken to ensure that both viral producer and target cells were in optimal condition at the time of infection, some variability undoubtedly occurred and may account for changes in frequency of G418^r colonies. For example, the fetal liver samples underwent considerable manipulation, and the plating efficiency of uninfected cells in progenitor assays was highly variable. Changes affecting the ability of hemopoietic progenitors to form colonies in culture might even more profoundly reduce the frequency of successful gene transfer. If so, this would account for data such as the low numbers of G418^r BFU-E after infection of fetal liver cells with virus from PA12/N2 producer cells (Table 1).

Although encouraging, the frequency of gene transfer demonstrated to primary progenitors by these data is still much lower than the theoretical 100% that should be obtainable with retroviruses.¹ Our frequencies are reasonably close to those reported by Hock and Miller for gene transfer to primary normal human hemopoietic progenitors from bone marrow¹² but are much lower than the 75% to 100% frequency reported by Eglitis et al for murine CFU-S.⁶ However, it is notable that the latter authors and others have found the level of expression of G418 resistance or *neo'* gene product to be highly variable among different CFU-S containing the *neo'* gene.⁴⁻⁶ The frequencies of G418 resistance in murine CFU-GM infected and selected *in vitro* have been approximately 10% to 30%,^{4,5} which is also lower than one might have predicted and consistent with our results on human progenitors.

A large number of techniques exist for transporting genetic material into cells. A number of these have been applied to primary hemopoietic progenitors, including calcium phosphate co-precipitation and electroporation.²⁴⁻²⁶ Although initial results using the former technique to confer methotrexate resistance on murine bone marrow cells appeared promising, similar results have not been forthcoming for other genes or for human cells. Electroporation is a relatively new technique that has not been widely applied to gene transfer into primary cells. Initial results with human bone marrow progenitors demonstrate low levels of transfer and expression of the xanthine-guanine phosphoribosyl transferase gene in CFU-GM.²⁶ The full potential of this technique remains to be explored. At the present time the bulk of evidence would indicate that the highest efficiencies of gene transfer are those mediated by retroviruses. Where high frequencies of transformation are necessary and appropriate vectors are available, these viruses appear to be the current method of choice for transporting genes into cells.

The knowledge gained from the present studies should facilitate the successful use of the technique of retroviral-mediated gene transfer to study genetic factors important in

normal and malignant hemopoiesis. In addition, there are a number of inherited human hematologic disorders that are known to have a molecular genetic etiology. Some of these may ultimately be curable by gene replacement therapy, possibly with retroviruses providing the means of transporting the normal gene into primitive hemopoietic progenitors.²⁷

ACKNOWLEDGMENT

The authors thank Dr A.D. Miller for the PA12 and PA317 cell lines and many helpful discussions, Dr R. Mulligan for providing the ψ 2 and ψ AM cell lines and pZipNeo DNA, and Dr E. Gilboa for pN2 DNA. They also thank Dr C.J. Eaves for reviewing the manuscript and for her useful comments.

Structural Polymorphism of Glycophorins Demonstrated by Immunoblotting Techniques

Yi-Qing Lu, Margaret E. Nichols, William L. Bigbee, Ronald L. Nagel, and Olga O. Blumenfeld

We have explored the polymorphism of the glycophorin system in the human erythrocyte membrane using the immunoblotting techniques and examining 52 individuals selected without prior bias as to their serologic state and ten documented serologic variants of M, N, S, s blood group system. Polyclonal antisera to α glycophorin and to α glycophorin CNBr carboxyl terminal fragment C (residues 82-131) and M and N specific monoclonal antibodies (MoAbs) were used. The first two reagents detect specific regions of the α glycophorin molecule and all electrophoretically resolved species of glycophorins immunologically related to α and δ glycophorins (δ glycophorin, [α - δ] hybrids and other glycophorins with an alteration in the carboxyl terminal segment); the M and N MoAbs identified the glycophorin species containing or lacking the M or N

determinant in the amino terminal octapeptide structures. We find that (1) immunoblotting confirmed in all cases the serologically determined phenotype; we also find that polymorphic forms of the glycophorin system are relatively infrequent; (2) immunoblotting, independent from serologic testing, was capable of detecting five mutants, two most like γ S-s-U-phenotypes; (3) a new glycophorin species was detected in normal red cells with both antiglycophorin and antipeptide C sera, which is not evident with MoAbs; (4) immunoblots of known glycophorin variants (En(a-), U-, M^a, Mi I, II, III, V, and St^a) confirmed but also extended our knowledge of the abnormal glycophorins involved; and (5) the He⁺ and Wr^b(-) cells showed normal patterns.

GLYCOPHORINS are a family of erythrocyte membrane glycoproteins, and in each individual several related forms are present.^{1,2} In the major M and N α glycophorins,^{*1} the antigens that determine the M, N blood groups reside; these glycoproteins differ in two amino acids at residues 1 and 5 of the polypeptide chain and are products of two codominantly expressed allelic genes.¹⁻⁶ Moreover, δ glycophorins, in which the S and s blood group antigens reside, are specified by other allelic genes⁶⁻⁸; these relatively less abundant glycophorins are related to the N form of α glycophorin but show amino acid sequence differences and lack the asparagine-linked oligosaccharide and the carboxy terminal segment of α glycophorin.^{1,7-9} The β and τ glycophorins are minor components whose serologic and structural characteristics are less clear.^{1,2}

As shown by recent gel electrophoretic and structural

studies, erythrocytes of serologic variants of the MNSs locus may exhibit additional variant forms of glycophorins. Blood group specific M^a, M^c, Mi I, and II erythrocytes contain products of variant alleles of the M or N genes,¹⁰⁻¹³ and those of St^a, Miltenberger V, or Ph individuals contain fusion glycophorins originating from recombination events between α and δ glycophorin genes.¹⁴⁻¹⁸ Some individuals and their families are known whose erythrocytes do not bear either α (En(a-)) or δ glycophorins (S-s-U-)^{1,2}; and others have cells that contain α glycophorin glycosylation variants, for example the Cad phenotype.^{19,20}

In this report we examined two aspects of glycophorin polymorphism using immunoblotting approaches. First, the extent of occurrence of glycophorin variants in a population of 52 individuals, selected without prior bias as to their serologic state; and second, the ability to be detected and the nature of profile differences in erythrocytes of individuals with serologically defined variant M, N, S, and s phenotypes.

MATERIALS AND METHODS

Preparation of erythrocytes. Random control erythrocytes were obtained from laboratory personnel and from 41 medical students from Central Africa (Cameroon, Zaïre, and Central African Republic).^{†2} Venous blood (collected with heparin or citrate-phosphate-dextrose) was centrifuged at 3,000 rpm for 30 minutes and plasma and buffy coat removed by aspiration. The erythrocytes were washed three times with isotonic phosphate buffer pH 7.6, followed by two washes with the same buffer containing inhibitors of proteolysis: 1 mmol/L phenylmethylsulfonylfluoride (PMSF), 2 mmol/L N-ethyl maleimide, and 0.02% sodium azide. Washed cells were centrifuged at 2,000 rpm for 15 minutes and used for blood typing and gel electrophoretic studies.

Serologically variant erythrocytes were obtained from individuals referenced in the rare donor file at New York Blood Center; their phenotypes are noted in Table 1. These cells had been frozen in

*Glycophorins will be designated essentially as proposed by Anstee²; α glycophorin is equivalent to glycophorin A or PAS-1 and PAS-2 glycoproteins, δ glycophorin is equivalent to glycophorin B or PAS-3; γ glycophorin is equivalent to glycophorin C and glycoprotein E (See Fig 1).² Fusion hybrids are glycophorins in which the amino terminal portion of the molecule has a sequence identical to one type of glycophorin, whereas the carboxyl terminal portion arises from another type of glycophorin. Unequal crossing over may be a genetic mechanism involved in the generation of these fusion hybrids.

liquid nitrogen and were reconstituted by adding a few frozen droplets at a time to 5 mL of saline solution at 45 °C.^{21,22} The cells were washed three times in saline and processed as described above for the freshly collected cells.

Blood group typing. Hemagglutination was performed according to standard procedures using commercial rabbit anti-M and anti-N sera (Ortho Diagnostic Systems, Raritan, NJ).

Polyacrylamide gel electrophoresis. Gel electrophoresis was carried out on 10% to 15% gradient gels in 0.1% sodium dodecyl sulfate (SDS) with a 3% acrylamide stacking gel as described by Laemmli.²³ Erythrocytes were prepared for electrophoresis as follows: to 0.025 mL of packed cells was added 0.5 mL of distilled water, followed by 0.25 mL of 3x sample buffer.²³ The solution was immersed for one minute in boiling bath and 10 μ L loaded into each of 20 slots of the slab gel. The remaining solution, in 0.1-mL aliquots, was kept at –20 °C. No change in electrophoretic patterns was observed on replicate analyses of the frozen samples.

Western immunoblotting. Immunoblotting was performed as described by Towbin et al.²⁴ Following electrophoresis the proteins in the unstained gels were electrophoretically transferred to nitrocellulose sheets in a Trans-Blot Cell (Bio-Rad) at 100 mA for 16 to 18 hours, using a transfer buffer consisting of 50 mmol/L Tris, 192 mmol/L glycine, and 20% (wt/vol) methanol. The blots were blocked with 7% bovine serum albumin, rinsed with 0.05 mol/L Tris-HCl-0.15 mol/L NaCl (pH 7.6), and incubated for one hour at room temperature with the appropriate antibodies, either antiglycophorin serum (1:200 dilution), antiserum to CNBr carboxyl-terminal fragment C (1:200 dilution), M-specific monoclonal antibody (MoAb) (1:5 dilution of culture supernatant fluid), or N-specific MoAb (1:100 dilution of purified immunoglobulin from ascites fluid, 1 mg/mL). In the case of the MoAbs the nitrocellulose

sheets were first exposed to rabbit antimouse IgG (1:750 dilution). One per cent bovine serum albumin was used for all dilutions. The nitrocellulose sheets were washed with 1% Tween in the above buffer and incubated with ¹²⁵I-Protein A prepared as described.²⁵ Following extensive washing with the Tween-buffer solution, the nitrocellulose blots were exposed to Kodak XAR-5 film for 1.5 to 3.0 days.

Preparation and properties of antisera and antibodies. Antisera were prepared in rabbits against α glycophorin prepared from erythrocyte membranes of an MN individual and against carbohydrate-free carboxyl terminal peptide C (residue 82–131) obtained by CNBr cleavage of α glycophorin.^{18,26} Both antisera react with M, N α glycophorin and its carboxyl terminal peptide C but do not react with the internal carbohydrate-rich portion of α glycophorin (CNBr peptide B, residues 9–81).¹⁸ Preimmune rabbit sera showed no bands when tested with purified glycophorins; with preparations of intact M, N, or MN erythrocytes a very faint band was seen at the position of band 5 similar in intensity to that seen in En(a—) cells (Fig 1; Ena(—) lanes A and B). More generally the specificity of the antisera is demonstrated by the pattern of reaction with the Ena(—) cells (lane B).

An M-specific MoAb (1–2–D9) was produced as previously described for MoAbs G8 and E₃.²⁷ The N-specific MoAb (NN 5) has been previously described.²⁸ The M MoAb reacted exclusively with the M α glycophorin and the N MoAb reacted with N α and δ glycophorins when tested on Western immunoblots with M and N α glycophorins isolated from MM or NN erythrocytes.¹⁸ The specificities of antisera and antibodies are summarized in Table 2. Preimmune mouse serum showed a faint band slightly below the position of band 2 and a much stronger band at the position of band 5 when tested with MN or NN erythrocytes (see Fig 1 for designation of glycophorin bands).

Fig 1. Fluorographs of immunoblots of erythrocytes of serologically "normal" MM, NN, MN representative individuals and an individual of the uncommon En(a-) phenotype. Lanes A, treated with antiglycophorin serum; Lanes B, with anti-peptide C serum; Lanes C, with M MoAb; Lanes D, with N MoAb. Identical aliquots of solubilized erythrocytes from each individual were subjected to electrophoresis on a single or different slab gel that were then processed as described. The fluorograms were photographed and lanes obtained with the respective antisera or antibodies were cut out and collated to display for each individual the reaction under each of the four conditions (lanes A to D). When electrophoresis was carried out on different slab gels, the mobility of bands was close but not always identical; for example, in En(a-) cells, lanes A and D are not exactly coincident. The numbers on the left identify bands that react with antiglycophorin serum. Bands denoted by the prime symbol ' are those that were not seen in serologically "normal" individuals. Replicate analyses of erythrocytes of each individual were carried out with all four reagents. In all cases identical patterns were obtained when conditions described in the text were used.

RESULTS

Glycophorins in erythrocytes of MN individuals. Erythrocytes of random individuals displayed seven bands on SDS-polyacrylamide gels when probed with the polyclonal antiserum to α glycophorin. This is shown in Fig 1 (lanes A), for erythrocytes of three representative MM, NN, and MN

individuals of 52 individuals examined. Bands 1 and 4 correspond to the α glycophorin dimer and monomer, respectively; bands 3b and 6 migrate in the area of δ glycophorin dimer and monomer, and band 5 corresponds to γ glycophorin (Table 3). In addition to these well-established bands,² an

additional band designated 3a is seen. β -Glycophorin bands, noted by others,² were not visualized and probably co-migrate with the monomer of α glycophorin (band 4).

As shown in Fig 1 (lane B) and Table 3, the antiserum to the carboxyl-terminal peptide C does not react with δ glycophorin in bands 3b and 6 but reacts with the other glycophorins. This confirms that δ glycophorin differs from α glycophorin either by an alteration in the carboxyl-terminal region or by the absence of that region. This also suggests that the minor glycophorins in bands 2, 3a, and 5 are structurally related with respect to that polypeptide region to α rather than to δ glycophorin.

The monoclonal M- and N-specific antibodies react with α glycophorins according to the M or N serologic phenotype of the cells; in addition, the N-specific MoAb reacts with δ glycophorins, even in the M positive cells (Fig 1, lanes C and D, Table 3). It was observed that in all the erythrocyte samples tested, band 3a was not demonstrated by either MoAb whereas band 5 was evident with both. The reactivity of pre-immune mouse serum at band 5 but not at bands 1 and 4, for example, suggests a specific antigen/antibody reaction rather than a nonspecific binding effect. It would appear therefore that some of the glycophorins recognized by pre-immune mouse serum also carry M- and N-specific epitopes recognized by the monoclonal reagents.

The glycophorin band profiles observed were all essentially similar for the 52 randomly chosen individuals. The only deviations observed were the absence of δ glycophorin in two individuals and the absence of band 5 using anti-peptide C serum in three individuals. The latter observation suggests that a structural alteration exists in the carboxyl terminal region of these glycophorins. The erythrocytes of the two former individuals could possibly exhibit the S- s- U- blood group phenotype. Unfortunately, fresh red cells were not available for confirmatory blood typing tests to be performed.

Glycophorins in erythrocytes with variant serologic phenotypes. Erythrocytes from ten different individuals exhibiting variant or null glycophorin phenotypes were examined

(Table 1). The altered glycophorin profiles became apparent when the cells were probed with the polyclonal antibody to α glycophorin (Figs 1 to 3). Thus in En(a-) cells the usual α glycophorin bands were absent, and in U- cells the δ glycophorins were absent; and in Mi I, II, III, V, and St^a cells, variant glycophorins (denoted as prime, ') could readily be detected by their electrophoretic mobilities, which were distinct from the usual glycophorin bands. In the case of M^a homozygous erythrocytes, the variant nature of α glycophorins was apparent because they did not react with the M- or N-specific MoAbs. These observations, summarized in Table 1, are essentially in agreement with reported findings.^{1,2,10-18,29,30}

Additional aspects of the structure of the altered glycophorins were apparent from the known specificities of the antisera and antibodies used. For example, the variant glycophorin in band 4' in MiII erythrocytes did not react with either M or N MoAb; in contrast, this band was distinctly evident with MiII cells and the M MoAb (Fig 2). Clearly the amino terminal region of this glycophorin in Mi I and Mi II cells is different. Bands 3b and 6 in En(a-) erythrocytes appear to contain the dimer and monomer of δ glycophorin from their reaction with antiglycophorin serum, the N MoAb, and lack of reaction with anti-peptide C serum. In addition to having no α glycophorin, these cells also lack the glycophorins in bands 2 and 3a seen in "normal" cells. However, at the position of band 5 these erythrocytes contain a glycophorin that reacts with both M and N MoAbs (a double band is seen with the N MoAb; Fig 1). Glycophorins in bands 2'' and 4' in Mi III cells resemble δ glycophorin in that they fail to react with anti-peptide C serum. They are probably variant forms of δ glycophorins whose usual 3b and 6 bands are less evident and appear to react with anti-peptide C serum.

Glycophorin bands 2', 2'', and 4' in Mi V cells appear to be variant forms of δ glycophorin, as they do not react with anti-peptide C serum; indeed it has been proposed that they are (α - δ) glycophorin hybrids.¹⁶ In contrast, St^a glycophorin variant bands 2', 2'', and 2''' react with anti-peptide C serum

Fig 2. Fluorographs of immunoblots of variant MiI, MiII, MiIII, MiV, and St^a erythrocytes. Lanes A, treated with antiglycophorin serum; lanes B, with anti-peptide C serum; lanes C, with M MoAb; lanes D, with N MoAb.

Fig 3. Fluorographs of immunoblots of U-NN, He⁺, Wrb⁽⁻⁾, and M^g erythrocytes. Lane A, treated with antiglycophorin serum; lanes B, with anti-peptide C serum; lanes C, with M MoAb; lanes D, with N MoAb.

and with the N MoAb; this supports their proposed (δ - α) hybrid structure.^{14,15,18}

The glycophorin profiles of He⁺ and Wrb⁽⁻⁾ cells are similar, under all conditions, to those of "normal" erythrocytes (Fig 3).

DISCUSSION

Using gel electrophoresis followed by immunoblotting, we demonstrate the extent of structural polymorphism of glycophorins in randomly chosen individuals, as compared to known serologic variants of the M, N blood group system.

The polyclonal antiserum to α glycophorin of an MN individual is an excellent reagent for the visualization of most molecules of the glycophorin family, and the antiserum to the carboxyl-terminal peptide of α glycophorin as well as the M and N MoAbs provide insight into the integrity of specific regions of the glycophorin molecule. In particular, this approach allowed us to identify the δ glycophorin and its variants and to detect glycophorins with altered amino terminal regions.

The presence of multiple bands in the gel patterns reflects partly the monomer-dimer relationship of α and δ glycophorins. Some bands observed in "normal" cells may represent other members of this family of proteins, for example, glycophorins in bands 3a and band 5. Glycophorin in band 3a may be a variant, and its lack of reaction with M and N MoAbs may be due to a sequence alteration or a lack of glycosylation within the amino terminal region. Reaction of the glycophorin in band 5 with both MoAbs in erythrocytes of all individuals of either M or N blood type is puzzling. Our findings could be explained by co-migration with γ glycophorin of minor glycophorins carrying M and N epitopes; no such glycophorins have been described. These glycophorins are thought to be related to α glycophorins since they all react with the antiserum to peptide C.

The mostly invariant glycophorin profiles as determined here among the 52 individuals suggest that electrophoretically definable variants are relatively infrequent. In addition, as part of another study,³¹ 54 individuals (with different pathologies) were also found to have identical glycophorin patterns, confirming that immunoblotting-definable glycophorin variants are rare. These observations complement the serologic findings of low incidence of variants of M, N, S, s blood groups.⁶ Nevertheless, in our series of 41 Africans, two individuals whose profiles are different lack δ glycophorin, and their phenotype is most likely S-s-U-. The frequency of approximately 5% observed here confirms the reported serologically defined frequency for the ethnic group we examined (Bantu-speaking Africans).³² This frequency is high enough to qualify for a selection-balanced polymorphism and because glycophorins have been implicated in *plasmodium falciparum* invasion, this relationship is worth pursuing. The structural difference in glycophorin of band 5 that was observed with the other three individuals has not been reported previously.

Our results with the serologically variant erythrocytes confirm and amplify the observations of other laboratories. This proved particularly significant in the case of hybrid glycophorins as found in Mi V or St^a cells^{13-16,18} where reaction with anti-peptide C serum or with the MoAbs could differentiate between the α - δ or δ - α hybrids and provided evidence that En(a⁻) cells used contained δ glycophorin. The use of the M and N MoAbs also confirmed the structural alteration in M^g glycophorin^{10,11} and in addition allowed us to conclude that Mi I glycophorin in band 4' was altered in the amino-terminal region and differed therefore from the analogous protein in MII cells.

The lack of an abnormal pattern in He⁺ and Wrb⁽⁻⁾ erythrocytes could be due to structural alterations of glycophorins that cannot be detected by the antisera used or to

mutations that do not alter the SDS-electrophoretic banding pattern.

Our results indicate that the erythrocytes of eight of ten MNSs blood group variants, documented serologically, show differences from the "normal" cells in electrophoretically resolved glycophorin profiles and clearly demonstrate that serologic deviation is a manifestation of structural variation in one or more members of the glycophorin family of molecules.

In a related approach, interactions with specific lectins have been used to probe variant glycophorin molecules resolved by gel electrophoresis of erythrocyte membrane proteins.³³ Merry et al used a series of MoAbs to α glycophorin to quantify the number of sites per erythrocyte.³⁴ In a

recent study Langlois et al proposed the use of flow cytometric analysis of erythrocytes labeled with specific glycophorin MoAbs to detect and analyze variant forms of glycophorins.³⁵

We conclude from this study that immunoblotting techniques, with a carefully selected battery of polyclonal and monoclonal antibodies, are capable of providing an accurate qualitative picture of polymorphism of the glycophorin system, significantly amplifying serologic analyses.

Shear-Induced Platelet Aggregation Requires von Willebrand Factor and Platelet Membrane Glycoproteins Ib and IIb-IIIa

By D.M. Peterson, N.A. Stathopoulos, T.D. Giorgio, J.D. Hellums, and J.L. Moake

Different types of platelets in various types of plasma were subjected to levels of shear stress that produce irreversible platelet aggregation in normal platelet-rich plasma (PRP). At shear stresses of 90 or 180 dyne/cm² applied for 30 seconds or five minutes, aggregation was either absent or only transient and reversible using severe von Willebrand's disease (vWD) PRP (<1% von Willebrand factor, vWF); Bernard-Soulier syndrome (BSS) PRP (platelets deficient in the membrane glycoprotein Ib, GPIb); normal PRP plus monoclonal antibody (MoAb) to GPIb; thrombasthenic PRP (platelets deficient in membrane glycoprotein IIb-IIIa complex, GPIIb-IIIa); and normal PRP plus MoAb to GPIIb-IIIa. Shear-induced aggregation was inhibited under the above conditions, even though the platelets were activated

to release their granular contents. Sheared normal platelets in vWD plasma aggregated in response to added vWF. These studies demonstrate that the formation of stable platelet aggregates under conditions of high shear requires vWF and the availability of both GPIb and GPIIb-IIIa on platelet membranes. The experiments demonstrate that vWF-platelet interactions can occur in the absence of artificial agonists or chemical modification of vWF. They suggest a possible mechanism for platelet aggregation in stenosed or partially obstructed arterial vessels in which the platelets are subjected to relatively high levels of shear stress.

© 1987 by Grune & Stratton, Inc.

PLATELET aggregation induced by various agonists in plasma is dependent on the binding of plasma proteins to specific ectoglycoprotein receptors on platelet surface membranes.¹ Ristocetin, a cationic glycopeptide antibiotic, artificially promotes platelet clumping in vitro by inducing the binding of large factor VIII-related von Willebrand factor (vWF) multimeric forms to or near to platelet membrane glycoprotein Ib (GPIb) molecules. Adenosine diphosphate (ADP), which is released (along with serotonin) from the dense granules of stimulated platelets, promotes platelet aggregation by inducing the attachment of fibrinogen to platelet membrane glycoprotein IIb-IIIa complexes (GPIIb-IIIa). Thrombospondin, a protein released from the α -granules of stimulated platelets, stabilizes fibrinogen binding to platelet surface glycoprotein IIb-IIIa complexes. Thrombin-stimulated platelets are altered in a manner that enables their glycoprotein IIb-IIIa complexes to bind fibrinogen, thrombospondin, fibronectin, and, with low affinity, vWF multimers.² Thus vWF is capable—under different circumstances—of binding both to glycoprotein Ib and to the glycoprotein IIb-IIIa complexes on platelet surfaces.

Patients with severe von Willebrand's disease (vWD) have an inherited bleeding disorder associated with the near absence of vWF multimers from their plasma and from their platelet α -granules.³ Von Willebrand's disease platelets have normal platelet receptors for vWF multimer binding,⁴ and platelet aggregation in severe vWD PRP is normal in response to ADP and other agonists except ristocetin. The giant platelets of patients with the congenital bleeding disorder Bernard-Soulier syndrome (BSS) lack platelet membrane GPIb¹ and cannot bind vWF or aggregate in the presence of ristocetin.⁴ Platelets in BSS PRP aggregate to ADP and other agonists. The platelets of patients with the severe form of the hereditary bleeding disorder Glanzmann's thrombasthenia lack the platelet membrane GPIIb-IIIa complex.¹ Platelets in thrombasthenic PRP aggregate in response to the ristocetin-induced binding of vWF multimers.⁴ ADP, epinephrine, and thrombin require for aggregation the binding of fibrinogen to the GPIIb-IIIa complex and, therefore, do not induce the aggregation of thrombasthenic platelets.¹

Fluid shear stress applied in vitro to normal PRP can itself induce platelets to aggregate and secrete their granular contents in the absence of added agonists.⁵⁻⁹ Shear stress may reach levels as high as 200 to 400 dyne/cm² when arterial vessels become stenosed or partially occluded,¹⁰⁻¹² as by arteriosclerosis or during vascular spasm. Thus platelet aggregation induced by shear stress may be of considerable importance both in normal hemostasis¹³ and in the pathophysiology of thrombus formation in small arteries, arterioles, and capillaries of the microcirculation.¹⁰

The present study was undertaken to evaluate the dependence of shear-induced platelet aggregation on plasma vWF and on platelet GPIb and the IIb-IIIa complex and to study their involvement in the mechanism of shear-induced platelet aggregation.

MATERIALS AND METHODS

Whole blood samples were collected from 12 healthy adults and three patients into siliconized test tubes containing 0.38% sodium citrate as anticoagulant (one volume of anticoagulant to nine volumes of blood). The patients had severe vWD (one patient; plasma and platelet vWF levels <1% of normal); BSS (one patient); and thrombasthenia (one patient).^{4,14,15} All have had life-long mucosal and posttraumatic bleeding and prolonged template bleeding times. Platelet-rich plasma (PRP) and platelet-poor plasma (PPP) were prepared by centrifugation as described elsewhere.⁹ The PRP

platelet count was adjusted to 300,000/ μ L with PPP. BSS PRP had a platelet count of 50,000/ μ L; however, the BSS platelets were four times the mean volume of normal platelets.

The PRP samples were subjected to controlled shear stress levels in a stainless steel cone-plate viscometer⁹ (Ferranti Electric Model 781) at 24 °C. Shear stress-induced platelet aggregation in this instrument has been demonstrated to be independent of any minimal platelet-surface interactions.⁹ There was also no measurable attachment of vWF antigen or particular multimeric forms to the surface of the viscometer, with or without the application of shear stress, as studied by methods described elsewhere.¹⁶ The number of shear experiments with normal and patient PRP were normal PRP, 25 experiments; severe vWD PRP, four experiments; BSS PRP, four experiments; and thrombasthenic PRP, two experiments.

Some normal PRP samples were incubated for five minutes with monoclonal antibodies (MoAbs) prior to shearing in concentrations of 6 μ g/mL (6D1 antibody against GPIb; ten experiments with five normal PRP samples); 10 μ g/mL (10E5 antibody against the GPIIb-IIIa complex; six experiments with five normal PRP samples); or 20 μ g/mL (control MAB31 antibody that binds to an undefined platelet membrane antigen and produces no functional defect; four experiments with two normal PRP samples). Monoclonal antibodies to GPIb (6D1) and GPIIb-IIIa complex (10E5) were generously provided by Dr Barry S. Collier of the State University of New York at Stony Brook, and we are grateful for his important contribution. The control MAB31 MoAb was produced in our laboratory by methods described by Collier et al.^{17,18}

After shearing, 10 μ L of PRP samples were dispensed in 20 mL of Coulter Isoton II diluent containing 0.5% glutaraldehyde and were counted. Particle count and size distribution were done with an electronic particle counter (Coulter Electronics Model ZB1 with Channelyzer) using a 50 μ m diameter aperture. Particles with sizes $\pm$ 20% of the mean platelet distribution of the unsheared PRP were considered as "single platelets." It is known, of course, that this size distribution range includes some small aggregates consisting of doublets and triplets. However, studies in which EDTA was used to disaggregate control samples suggest that the "single platelets," as reported here, agree with the actual platelet numbers (EDTA-treated) to within about 30%. The disappearance of "single platelets" was accounted for by the formation of platelet aggregates; thus the percent decrease in "single platelets" is directly related to the percent increase in platelet aggregates. Lactic dehydrogenase activity (LDH) and ¹⁴C-serotonin release from platelets were measured by methods described previously.^{7,8}

Large vWF multimeric forms were purified from normal human cryoprecipitate by the method of Thorell and Blomback.¹⁴

RESULTS

The dependence of shear-induced platelet aggregation on plasma vWF and on platelet GPIb and the GPIIb-IIIa complex is shown in Figs 1 and 2. Normal platelets sheared in normal plasma at 90 or 180 dyne/cm² for varying times were aggregated extensively. Exposure to shear stress for 30 seconds or more resulted in platelet aggregation that could be observed directly and microscopically and was quantified as a decrease in the number of single platelets by nearly 80%. After five minutes of shearing some platelets disaggregated, as shown by the increase in particle count; however, about 50% remained in stable aggregates. In contrast, stable platelet aggregates failed to form in the shear fields using PRP from a patient with severe vWD; BSS (deficient in the ristocetin-induced binding component of GPIb);^{4,15} throm-

Fig 1. Effects of shear stress and shearing time on normal (○), Bernard-Soulier (□), severe von Willebrand's disease (vWD) (▲), and anti-GPIb antibody-treated (Δ) platelet-rich plasma. In (A) shear stress was 180 dyne/cm²; in (B) shearing time was five minutes. Symbols represent mean values and bars one SD.

basthenia (deficient in the GPIIb-IIIa complex);^{4,19} and normal individuals in the presence of MoAbs either to GPIb or to the GPIIb-IIIa complex.^{17,18} The shear-induced increases in particle counts observed in the BSS, thrombasthenic, and anti-GPIIb-IIIa-treated PRP was presumably due to dissolution of some microaggregates that were initially present before application of the shear field.

The control MoAb (MAB31) that binds to human platelets at a site other than GPIb or the IIb-IIIa complex did not impair shear-induced platelet aggregation in PRP, as shown in Fig 2.

PRP consisting of normal platelets in severe vWD plasma prepared by methods described elsewhere,²⁰ sheared at 180 dyne/cm² for 30 seconds or five minutes, failed to produce aggregates (data not shown). Immediately following the shearing, PRP samples placed in an aggregometer aggregated in response to added vWF (100 U/dL). This extent of aggregation was significantly higher than in nonsheared PRP samples. Sheared PRP samples, which were incubated for five minutes after the shear, aggregated in response to added vWF to a degree intermediate between the unsheared control and the sheared but not incubated specimen. Other results (not shown) revealed that vWF did not attach to the viscometer and that vWF multimeric forms were not altered in the shear field.

Fig 2. Effect of time in the shear field on normal (○), thrombasthenic (□), anti-GPIIb-IIIa antibody-treated (Δ) control monoclonal antiplatelet antibody (MAB31)-treated (▲) platelet-rich plasma sheared at 90 dyne/cm² (A), and 180 dyne/cm² (B). The bars denote one SD.

Fig. 3. Effect of shear stress on ^{14}C -serotonin release from normal (○), Bernard-Soulier (□), anti-GPIb antibody-treated (△), and anti-GPIIb-IIIa antibody-treated platelets (▲) in platelet-rich plasma sheared for five minutes.

Platelets in the different types of samples released ^{14}C -serotonin in response to shear stress (Fig 3). These results indicate that activation of the platelets occurred in the shear fields, even when there was little or no aggregation.

DISCUSSION

The present study has demonstrated that vWF and the availability of both GPIb and the GPIIb-IIIa complex on platelet membranes are essential for aggregation at relatively high shear stresses, as may be attained in stenosed or partially occluded arterial vessels.¹⁰⁻¹² No externally added agonist (eg, ristocetin) or chemical modification of vWF (eg, desialation) is required for this effect. Our findings are compatible with other observations¹³ that implied the

involvement of vWF in platelet thrombus formation in a flowing system and with a preliminary report²¹ of defective shear-induced platelet aggregation in vWD PRP. Our results may help to explain the disappearance of large vWF multimeric forms during acute episodes of systemic platelet aggregation in thrombotic thrombocytopenic purpura¹⁴ and during extensive intrarenal platelet aggregation in the hemolytic-uremic syndrome.²² Our results reported elsewhere²⁰ show that the large multimers are especially active in platelet-platelet binding in the shear field.

It is possible that vWF attachment to platelets is necessary but not sufficient to cause aggregation during the application of relatively high shear stresses. Additional plasma proteins may be involved. Our results confirm the possibility expressed by others^{23,24} that shear induces a direct alteration of platelet membrane GPIb and GPIIb-IIIa complexes. According to this hypothesis, vWF attaches predominantly to GPIb, and this binding further perturbs the conformation of GPIIb-IIIa; then additional vWF, along with fibrinogen (and, possibly, fibronectin), attach to the altered GPIIb-IIIa complexes and potentiate aggregation.

Gamma-Interferon in Aplastic Anemia: Inability to Detect Significant Levels in Sera or Demonstrate Hematopoietic Suppressing Activity

By Beverly Torok-Storb, Gretchen Gloor Johnson, Raleigh Bowden, and Rainer Storb

A radioimmunoassay (RIA) was used to quantitate biologically active gamma interferon (INF- γ) in sera and in supernatants of cultured mononuclear cells obtained from 50 patients with aplastic anemia. Only five of the 50 serum samples had INF- γ levels above background ($>0 < 0.5$ units per mL). Detectable levels of spontaneous INF- γ (0.3 to 868 U/mL) were found in 18 of the 50 mononuclear cell supernatants tested. The addition of patient sera or INF- γ positive supernatants to cultures of normal hematopoietic colonies did not result in reduced colony growth. Flow cytometric analysis of mononuclear cells failed to

establish a correlation between the presence of INF- γ in supernatants and the number of activated T cells or natural killer (NK) cells in the mononuclear cell population. However, a significant correlation did exist between the presence of monocytes and the production of INF- γ . Contrary to previous reports, our data suggest that patients with aplastic anemia do not have high circulating levels of INF- γ . Unstimulated mononuclear cells from some patients will produce significant levels of INF- γ , but this does not result in decreased *in vitro* hematopoiesis.

CELLS participating in a response to foreign antigen produce a cascade of lymphokines that serve to activate cellular functions required to direct and control the immune response. Among these lymphokines is a heterogeneous family of proteins known as interferons (INF). One species of INF referred to as immune or gamma INF (INF- γ) is produced by lymphocytes, particularly antigen-specific T cells and natural killer cells (NK).^{1,4} A recent review of INF- γ has summarized the multitude of effects attributed to this lymphokine.⁵ Among these effects is the inhibition of hematopoietic colonies grown *in vitro*.^{6,7} This observation, together with the detection of high levels of INF- γ in the serum of patients with aplastic anemia, has led to the hypothesis that INF- γ is the mediator of hematopoietic suppression seen in these patients.⁸

The experiments presented in this report were designed to test the role of INF- γ in hematopoietic suppression associated with aplastic anemia. The methodologies used took advantage of a recently developed solid phase radioimmune assay specific for biologically active INF- γ .⁹

MATERIALS AND METHODS

Patient samples. Included in this study were samples obtained from 50 patients with severe aplastic anemia. After informed consent whole blood was obtained by venipuncture prior to treatment. Blood was collected into preservative-free heparin, diluted 1:1 in Hanks' balanced salt solution, (HBSS) and layered over Ficoll-Hypaque for centrifugation at $400 \times G$ for 30 minutes. Interface mononuclear cells were collected, treated with hemolytic buffer, and washed three times as described previously.¹⁰ Serum samples were obtained from 3 mL clots, processed at 4 °C, and stored at -80 °C.

Interferon measurements. INF- γ was measured in a solid phase radioimmunoassay (RIA), which employs B1 antibody-coated polystyrene beads as the immunoadsorbent and ¹²⁵I-B3 antibody as a tracer (Centocor, Malvern, PA). Both the specificity of the monoclonal B1 and B3 antibodies and the sensitivity of the RIA have been described.^{9,11,12} Briefly, B1 and B3 are mouse monoclonal antibodies (MoAbs) specific for natural and *Escherichia coli*-derived recombinant human INF- γ . The two antibodies recognize different epitopes and do not compete for binding.

Two sources of recombinant INF- γ were used to test the sensitivity of the RIA. The first had a protein concentration of 1.4 mg/mL with an antiviral activity of 2.7×10^7 IU/mL, as determined by its ability to inhibit cytopathic effects (CPE) of vesicular stomatitis virus on human amnion WISH cells compared to NIH HuIFN- γ reference standard number G-023-901-527. When measured by the

RIA described above, this recombinant INF- γ had an activity of 7.78×10^6 U/mL. The second source of INF- γ had an antiviral activity of 2.0×10^6 (NIH reference) U/mL and 3.8×10^6 U/ml by RIA.

The biological activities of both sources were tested by their ability to augment NK activity against K562 tumor targets and were found to be consistent with their estimated degree of activity.¹³

Immunofluorescence labeling. Ficoll-Hypaque-separated peripheral blood mononuclear cells (PBMC) were resuspended at 1 to 3×10^6 in 0.1 mL of RPMI 1640 with 20% fetal bovine serum and then labeled as described.¹⁰ Briefly, an equal volume of MoAb at an optimal dilution was added and the cells incubated at 4 °C for 30 minutes, washed twice, and then incubated an additional 30 minutes with 0.05 mL of fluorescein isothiocyanate-conjugated goat F(ab)₂ antimouse antibody (diluted 1:10). Labeled cells were then washed, fixed in normal saline with 1% paraformaldehyde, and stored in the dark at 4 °C until analyzed.

Murine MoAbs specific for various human lymphohematopoietic surface antigens were used to label patient cells: antibodies 35.1 (CD2), 66.1 (CD4), 51.1 (CD8), all provided by Dr John Hansen, were used to identify various T cell populations; TAC antibody (a gift from Dr Tom Waldmann) was used to identify cells expressing the IL 2 receptor; antibodies 20.3 (CDw14), and 60.1 (CD11), also from John Hansen, were used to identify monocytes and granular lymphocytes, respectively; commercially available antibodies Leu-7 and Leu-11 were used to identify NK cells; antibody IF5 was provided by Dr Ed Clark for the identification of B lymphocytes.¹⁴⁻¹⁹

Cell sorter analysis. Fixed cells were analyzed by flow microfluorometry with use of a fluorescence-activated cell sorter (FACS IV, Becton Dickinson, Oxnard, CA) equipped with a five-decade

logarithmic amplifier. Glutaraldehyde-fixed chicken red blood cells were used as standards before each analysis. For each sample the intensities of forward light scatter, 90° light scatter, and green fluorescence were determined for 6×10^3 signals. Data was stored on a floppy disc for computer analysis. The fluorescence intensity of cells labeled with specific MoAbs was compared with that of cells treated with nonbinding control antibodies to determine the percent positive cells for a given surface determinant.

Tissue culture. Mononuclear cells were cultured for one to seven days, $\pm 50 \mu\text{g/mL}$ PHA, in 10% fetal bovine serum and RPMI 1640 at a concentration of 1 to 2×10^6 cells per mL. Cells were removed from the cultures by centrifugation and the supernatants stored at -80°C until analyzed for INF- γ levels or colony-inhibiting activity.

Ficoll-Hypaque-separated bone marrow cells (BMC) or PBMC from normal donors were used as a source of hematopoietic precursor cells assayed as erythroid burst-forming units (BFU-E) and granulocytic-monocytic colony-forming units (CFU-GM). Both were grown in 0.9% methylcellulose, with 10% to 20% pooled human serum, 2% bovine serum albumin, and 3.0 U/mL of partially purified erythropoietin (Terry Fox Laboratories, Vancouver, BC). An exogenous source of burst-promoting and colony-stimulating activities was provided as supernatant from the MO-cell line (a gift from Dr D. Golde) and PHA-stimulated leukocyte-conditioned media; each was added at a final concentration of 4%.

RESULTS

Sensitivity of the RIA. Figure 1 shows the linear relationship between bound ^{125}I -B3 antibody measured as counts per minute (cpm) and units per milliliter of INF- γ added by serial twofold dilutions of a standard recombinant INF- γ source. Comparable data were obtained with two additional sources of recombinant INF- γ . The assay is linear between 1 and 50 U/mL as reported; therefore samples with greater than 50 U/mL activity were diluted for a second measurement.

Stability of INF- γ . The stability of INF- γ in fresh human serum was evaluated. The data presented in Table 1 indicate that serum samples can be held at least 24 hours at 22°C before storage at -80°C without losing activity. Nevertheless, all patient sera were processed at 4°C within six hours of procurement and then stored immediately at -80°C until analyzed. The stability of INF- γ in culture media stored at -80°C was also assessed. Four culture supernatants containing detectable levels (47, 41, 22, 14

Fig 1. Standard curve showing the average counts per minute (cpm) on the vertical axis obtained for each of the INF- γ concentrations prepared as twofold serial dilutions of a recombinant INF- γ source. Background (ie, 0 $\mu\text{g/mL}$) averaged 159.5 cpm and was subtracted from all counts prior to calculation of the standard curve.

Table 1. Stability of INF- γ in Fresh Human Serum as a Function of Time Prior to Storage at -80°C

U/mL INF- γ Added	0 Minutes	Six Hours	24 Hours
2	875* (1.3)	766 (0.9)	887 (1.3)
4	1035 (1.9)	1392 (3.1)	1270 (2.7)
8	2421 (6.9)	2604 (7.6)	2512 (7.2)
40	15830 (37.1)	15020 (35.1)	14280 (33.3)

*Data represent cpm (U/mL INF- γ).

U/mL) were assayed a second time after an additional month of storage. The second measurement of all four samples (49, 37, 25, and 14, respectively) varied less than 10% from the original.

INF- γ in sera and supernatants. Forty-five of the 50 serum samples tested in this assay had no detectable amounts of INF- γ . Five samples had levels above background that were calculated to constitute less than 0.5 U/mL.

Mononuclear cells from bone marrow and peripheral blood were cultured with and without PHA for seven days. Culture supernatants were sampled daily and assayed for INF- γ . Figure 2A shows that plateau levels of INF- γ were obtained by day 3 from PHA-stimulated normal blood or marrow mononuclear cells and that no INF- γ was detected when PHA was not added to cultures. Figure 2B shows that plateau levels of INF- γ were also reached by day 3 in cultures of PHA-stimulated blood mononuclear cells obtained from four representative aplastic anemia patients. Cells from two patients produced significant levels of INF- γ without mitogen stimulation. Subsequently, supernatants were routinely harvested at day 3 from cultures of unstimulated patient peripheral blood mononuclear cells to assess spontaneous production of INF- γ . Detectable levels of INF- γ ranging from 0.3 to 868 (mean = 34.8) U/mL were observed in 18 of the 50 samples tested. Data on INF- γ production by patient marrow cells was not obtained because marrow mononuclear cells obtained from aspirates of patients either contained too few cells for culture or were so heavily contaminated with blood that they were indistinguishable by FACS analysis from PBMC.

Fig 2. Production of INF- γ U/mL by mononuclear cells cultured with PHA (solid circles) and without PHA (open circles); data obtained from normal blood derived (PBMC) or marrow derived (M) mononuclear cells is shown in (A), whereas data obtained from aplastic anemia patient PBMC are shown in (B).

Table 2. Comparative Analysis of Peripheral Blood Mononuclear Cells Used to Generate Cultured Supernatants Either Positive (Group A) or Negative (Group B) for Spontaneous INF- γ Production

	Group A n = 18	Group B n = 32
INF- γ U/mL	34.8 (0.3-890)*	0
Ratio helper:suppressor T cells	1.6 (0.3-2.9)	1.7 (0.6-4.6)
% IL2 receptor positive cells	10.6 (0-27.6)	10.8 (1.3-37.4)
% Leu-7 positive cells	12.5 (0-26.9)	17.6 (3.4-47.6)
% Leu-11 positive cells	11.4 (0-38.5)	10.1 (1.0-24.5)
% CD-11 positive cells	24.1 (6.6-47.4)	25.8 (8.1-87.7)
% Monocytes†	11.2 (2.0-24.1)	<1.6 (<1.0-8.5)‡

*Data are shown as mean (range) of all observations.

†Monocytes were identified by large size, failure to label with T and B cell specific antibodies, and positive labeling with antibodies 20.3 (CDw14), 60.1 (CD11), and p4.1 (HLA-DR).

‡Twenty-three of 32 samples in group B had <1.0% detectable monocytes; for computation of the mean these samples were scored as 1.0. Therefore our statistical analysis represents a very conservative estimate of the differences between group A and group B.

Flow cytofluorometric analysis. Indirect immunofluorescence labeling and flow cytofluorimetric analysis (FACS) was used to compare the composition of PBMC between samples that produced spontaneous INF- γ and samples that did not. As shown in Table 2, PBMC that produced INF- γ (group A) had the same helper:suppressor T cell ratios, percent activated T cells, and percent HNK-1 (Leu-7) positive cells as the PBMC that did not produce INF- γ (group B). In contrast to these similarities, the PBMC from group A had a significantly ($P < 0.001$) greater percentage of monocytes than found in group B. The majority of the PBMC populations in group B (23 out of 32) had less than 1% monocytes as determined by FACS analysis of 6×10^3 total cells.

INF- γ effects on hematopoietic colony growth. Supernatants from cultured PBMC were added at a final concentration of 10% to in vitro assays of hematopoietic precursors. Table 3 summarizes the data obtained in one representative experiment, which indicates that INF- γ positive supernatants had no significant effect on BFU-E or CFU-GM growth. All 18 INF- γ positive supernatants were tested in cultures of normal blood derived BFU-E. BFU-E numbers obtained in cultures with INF- γ positive supernatants ranged from 90% to 120% (mean 101.5) of growth obtained in control cultures without supernatants. Ten supernatants with no detectable INF- γ were also tested; BFU-E growth in the presence of negative supernatants ranged from 46% to 160% (mean = 94.3) of control growth.

Table 3. Representative Experiment Showing the Effect of Supernatants From Cultured Mononuclear Cells on the Growth of Normal Erythroid Burst Forming Units (BFU-E) and Granulocytic/Monocytic Colonies (CFU-GM)

Supernatants Added*	Mean $\pm$ SE colonies/ 10^5 Cells	
	BFU-E	CFU-GM
None	61 $\pm$ 0.7	24 $\pm$ 3.2
Normal (0 U/mL INF- γ)	52 $\pm$ 6.4	25 $\pm$ 2.7
Patient 1 (868 U/mL INF- γ)	58 $\pm$ 3.5	23 $\pm$ 1.8
Patient 2 (0 U/mL INF- γ)	64 $\pm$ 9.1	21 $\pm$ 3.3
Patient 3 (83.6 U/mL INF- γ)	51 $\pm$ 4.9	19 $\pm$ 2.7

*All supernatants were harvested from cultures of unstimulated PBMC at day 3 of incubation.

The effect of 10% patient serum on the growth of normal BFU-E was also evaluated. None of the 20 samples studied contained growth inhibiting activity (data not shown).

DISCUSSION

Severe aplastic anemia most likely results from several different pathogenic mechanisms.²⁰ Clinical data showing recovery in a proportion of patients after cytoreductive or immunosuppressive therapy strongly suggest that in some cases aplasia must be caused by mechanisms extrinsic to the stem cell.²¹⁻³⁰ Investigators have focused on activated T cells or NK cells and their products as the possible effectors of this mechanism with the stem cell or the putative hematopoietic regulatory cell as the target.³¹⁻⁴² Recently particular emphasis has been placed on INF- γ elaborated by activated T lymphocytes as the direct mediator of hematopoietic suppression.^{6-8,34,37-39}

Implicating INF- γ as a direct effector of hematopoietic suppression in vitro has primarily involved studies that used partially purified sources of INF- γ . Recent findings, however, suggest that even the most purified preparations of INF- γ have been contaminated with lymphotoxins that may be responsible for growth inhibition.⁴³ Recently Raefsky et al reported that colony growth could be inhibited with a homogenous preparation of recombinant INF- γ ; however, the extent of inhibition was influenced by culture conditions such that maximum inhibition required suboptimal concentrations of fetal bovine serum.⁴⁴ In contrast to this, Trinchieri and Perussia have reported studies that showed that even high doses of recombinant INF- γ did not significantly inhibit colony formation.⁵

The association of INF- γ with aplastic anemia came from the observations that relatively high levels of INF- γ could be detected in patient serum and in supernatants from cultured patient cells.⁸ The presence of INF- γ was determined in those studies by its ability to inhibit the cytopathic effects of vesicular stomatitis virus on human amnion WISH cells. The presence of INF- γ in serum of aplastic anemia patients seemed reasonable, since their peripheral blood mononuclear cells also contained an elevated number of activated lymphocytes that are reported capable of producing INF- γ . However, using a very sensitive and reproducible RIA specific for

biologically active INF- γ , we were unable to detect elevated levels of INF- γ in the serum of aplastic anemia patients.

The difference between our serum results and those previously reported could possibly be attributed either to a qualitative difference between patient groups or the possibility that the bioassay of virus inhibition may be detecting several activities, whereas the RIA is only detecting INF- γ . Ideally, the same serum samples should be evaluated in both assays. Recently Hinterberger et al, using both the standard bioassay and the Centocor RIA, reported that INF- γ was not detected in the serum of patients with aplastic anemia.⁴⁵

We also measured the release of INF- γ from cultured peripheral blood mononuclear cells (PBMC). PHA stimulated PBMC from both patients, and normals produced significant amounts of INF- γ , which reached plateau levels by day 3 of incubation. Unlike normal PBMC, cells from some patients released significant levels of INF- γ without PHA stimulation as previously reported.⁸ This spontaneous release also reached plateau levels at day 3. Therefore, all patients were subsequently tested for spontaneous INF- γ production at day 3 of culture; 18 of the 50 samples tested had detectable levels. All 18 supernatants were tested for their ability to inhibit growth of hematopoietic colonies, and none showed significant inhibition. As a group the INF- γ positive supernatants had the same effect on BFU-E growth as INF- γ negative supernatants. Sera from these patients had no inhibitory effect on normal BFU-E growth. These

observations are in agreement with those obtained by David Nathan and colleagues who studied a series of 15 patients and failed to demonstrate any inhibitory activity in patient sera (personal communication).

The ability of the cultured PBMC to produce INF- γ did not correlate with the presence of activated T lymphocytes or HNK-1 positive cells; however, INF- γ production was significantly ($P < 0.001$) correlated with the presence of greater than 1% monocytes.

Since INF- γ production by T lymphocytes and NK cells has been shown to be dependent upon the secretion of interleukins by accessory cells,⁴⁶ it is not surprising that we found an association between the absence of monocytes in patient PBMC and the inability of the PBMC to produce INF- γ . We cannot be certain at this time whether the relative paucity of monocytes recovered from the majority of patients reflects problems associated with cell separation and recovery or the real consequences of a disease process. If our assessment of monocyte number accurately reflects the in vivo situation, it becomes reasonable to hypothesize that insufficient numbers of monocytes could contribute to immune dysfunction, and given that the immune system may serve in some capacity to regulate hematopoiesis, such immune dysfunction could serve to maintain marrow failure. The data presented in this report, however, do not support the hypothesis that INF- γ is the direct effector of "immune-mediated" aplasia.

Inosine Monophosphate Dehydrogenase and Myeloid Cell Maturation

By Robert D. Knight, John Mangum, Diane L. Lucas, David A. Cooney, Ernest C. Khan, and Daniel G. Wright

In previous studies of purine ribonucleotide metabolism in the human myeloid leukemia cell line HL-60, we observed that there is a down-regulation of guanine ribonucleotide biosynthesis from the central intermediate, inosine monophosphate (IMP) and a depletion of intracellular guanosine triphosphate (GTP) and guanosine diphosphate (GDP) pools that occur during the induced maturation of these cells. We also found that inhibitors of IMP dehydrogenase, the enzyme that catalyzes the first step of guanylate synthesis from IMP, are potent inducers of HL-60 maturation. Because of these observations we specifically investigated the activity of IMP dehydrogenase in HL-60 cells and in a new inducible human myeloid leukemia cell line, RDFS2-25, both during maintenance culture and during induced maturation of the cells. Enzyme activity was examined directly in cell extracts with a radiometric assay that measures free $^3\text{H}_2\text{O}$ formed from $[2\text{-}^3\text{H}]$ IMP during the conversion of IMP to XMP. Uninduced HL-60 and RDFS2 cells in maintenance culture were found to have high levels

of IMPD activity (5.2 to 5.7 pmol IMP metabolized/ 10^7 cells/min) compared with normal neutrophils and monocytes that had been purified from blood (<1.5 pmol IMP metabolized/ 10^7 cells/min). However, when HL-60 and RDFS2-25 cells were induced to mature with retinoic acid (10^{-6} mol/L), dimethylformamide (6×10^{-2} mol/L), or a known IMPD inhibitor, tiazofurin (10^{-6} mol/L), IMPD activity in the cells fell by 51% to 80% within three to six hours. These changes in IMPD activity preceded detectable functional and antigenic maturation of the cells by at least 12 hours and were not temporally related to changes in cellular proliferation. These findings are consistent with the concept that the regulation of myeloid cell maturation may be influenced by intracellular concentrations of guanine ribonucleotides because IMP dehydrogenase activity is known to be rate limiting for the production of these nucleotides.

THE NEOPLASTIC cells of acute myelogenous leukemia are characterized by an inability to undergo normal terminal differentiation. However, defects of differentiation in leukemic cells are not necessarily complete. Leukemic cells may display variable degrees of maturity in individual patients,¹ and they may retain a capacity for spontaneous maturation when placed in primary tissue culture.² Furthermore, a number of continuously maintained, myeloid leukemia cell lines have been established that undergo maturation when exposed to a variety of chemical agents in vitro.³ Understandably these cell lines have attracted considerable investigative interest since they appear to provide an opportunity to define basic mechanisms underlying the blockade of terminal differentiation in leukemia.

The HL-60 cell line, originally isolated from the leukemic blasts of a patient with acute promyelocytic leukemia,⁴ has been the object of particularly extensive investigation. This cell line can be induced experimentally to undergo a form of terminal differentiation with which the cells acquire functional and morphological characteristics of mature neutrophils.⁵⁻⁷ In previous studies of HL-60 cells we showed that discrete changes in the intracellular production and supplies of guanine ribonucleotides guanosine triphosphate [GTP] and guanosine diphosphate [GDP] are associated with

induced maturation of these cells.⁸ Intracellular concentrations of guanine ribonucleotides were found to fall during HL-60 cell maturation, and this change could be attributed to diminished nucleotide biosynthesis. Furthermore, changes in guanylate production during induced maturation were not accompanied by comparable changes in adenylate production or in intracellular adenosine nucleotide concentrations.

Studies of purine nucleotide biosynthesis using radiolabeled precursors to examine both the de novo and purine salvage pathways during HL-60 cell maturation focused our attention upon the first step of guanylate biosynthesis from the central intermediate inosine monophosphate (IMP), catalyzed by the enzyme IMP dehydrogenase (IMPD). This step appeared to be the point at which guanylate biosynthesis is selectively down-regulated during induced maturation of these cells. We therefore examined the effects of known inhibitors of IMPD upon HL-60 cells and found that these agents (eg, mycophenolic acid, 3-deazaguanosine, and 2- β -D-ribofuranosylthiazole-4-carboxamide [tiazofurin]) not only selectively inhibit guanylate biosynthesis in the cells, as expected, but also induce the cells to mature.^{8,9}

These findings were of particular interest because of previous reports by others suggesting that IMP dehydrogenase activity in cells may be relevant to neoplastic transformation and/or to cellular maturity. Rat hepatoma cells^{10,11} and human leukemic blasts¹² have been found to express high levels of IMPD activity when compared to normal, differentiated cells of the same tissues. Moreover, such differences in IMPD activity, which distinguish normal from neoplastic cells, could not be explained simply by differences in cellular proliferation.¹¹

In the studies reported here, we used a radiometric assay of IMPD to study the activity of this enzyme directly in HL-60 cells and in a new human myeloid leukemia cell line, RDFS2-25.¹³

Cells were studied both in maintenance culture and during induced maturation. Results confirmed our impression that a down-regulation of IMPD occurs early during the induced

maturation of myeloid leukemia cells, and they lend support to the concept that the intracellular supplies of guanine ribonucleotides, which are determined by the activity of this rate-limiting enzyme for guanylate synthesis, may have a role in the regulation of myeloid cell maturation.

MATERIALS AND METHODS

Human myeloid leukemia cell lines. Continuous suspension cultures of the HL-60 cell line were established initially from seed cultures obtained from the laboratory of Dr Robert C. Gallo (National Cancer Institute, Bethesda, MD). Additional stocks cryopreserved at passage 11 following the original establishment of this line, were obtained from the American Type Culture Collection (Rockville, MD). Cells were maintained in RPMI 1640 medium supplemented either with 10% heat-inactivated (56 °C for 30 minutes) fetal bovine serum (Reheis Chemical, Phoenix, AZ) or with insulin (6 μ g/mL), transferrin (5 μ g/mL), and selenium (3 nmol/L) (Sigma, St. Louis). In our studies serum-free medium supplemented with insulin, transferrin, and selenium is referred to as ITS medium. Cells were cultured in 75-cm² tissue culture flasks (Falcon Plastics, Becton Dickinson, Oxnard, CA) and incubated at 37 °C in a continuously maintained environment with 7% CO₂ and 100% humidity. Cell counts in culture specimens were determined by hemocytometer chamber counting, and the viability of cells was assessed by dye exclusion using 0.1% trypan blue (MA Bioproducts, Walkersville, MD). Morphology of cells was examined with cytospin preparations stained by Wright-Giemsa. For maintenance cultures, cells were passed by resuspending them in fresh nutrient media at a concentration of 2×10^5 cells/mL every three to five days. Cells were studied at maintenance passages 20 to 30.

The RD62 cell line was isolated from the peripheral blood blasts of a 56-year-old man with acute myelogenous leukemia (FAB class M1).¹³ Shortly after diagnosis the patient died from a cerebral hemorrhage and was found to have diffuse leukemic infiltration of the brain, lymph nodes, and central organs. Leukocytes were obtained for culture at the time of diagnosis when the WBC count was 188,000/ μ L (71% blasts, 5% promyelocytes or myelocytes, and 2% lymphocytes). Leukemic blasts were peroxidase positive and α -naphthol butyrate esterase negative. These cells were separated from blood by Hypaque-Ficoll gradient centrifugation and then cultured in RPMI 1640 supplemented with 20% fetal bovine serum (Reheis), ITS, and 10% PHA-stimulated, human lymphocyte-conditioned media (LCM) at a cell concentration of 1×10^6 /mL. After three weeks initial culture at 37 °C with 7% CO₂, additional medium was added and then renewed weekly by demidepletion with gradual withdrawal of the fetal bovine serum (FBS) and LCM. By eight weeks cells were continuously maintained (average doubling time = 56 hours) in RPMI, ITS, and 10% FBS. These cells showed a limited but stable capacity to undergo induced myeloid maturation. This initial RD62 line was then cloned by limiting dilution, and derivative lines were isolated, which demonstrated either limited degrees of induced maturation or prominent myeloid maturation when exposed to inducing agents. Two such derivative lines, RD62-25 (inducible) and RD62-4 (noninducible), were examined in the studies reported here. Like the HL-60 cells, RD62 cells were resuspended in fresh nutrient media every three to five days. These cells were studied at maintenance passages 20 to 40.

Induced maturation of HL-60 and RD62 cells. Before IMPD levels were studied in leukemic cell lines during induced maturation, the cells were adapted to and maintained in serum-free ITS media for at least three passages. Cells in log-phase growth (two to three days following media change) were induced to mature by inoculation into fresh ITS media supplemented with a variety of inducing compounds. Final concentrations of inducing agents were retinoic

acid (Sigma), 1.0 μ mol/L; dimethylformamide (Eastman Kodak, Rochester, NY), 60 mmol/L; and 2- β -D-ribofuranosylthiazole-4-carboxamide (or tiazofurin, obtained from the Drug Synthesis and Chemistry Branch, DCT, NCI, NIH, Bethesda, MD), 1.0 μ mol/L. Induced maturation of the cells was assessed by previously described methods for determining NBT reduction,^{8,14} phagocytosis of opsonized yeast,⁸ and reactivity to the monoclonal antibody (MoAb) OKM1 (Ortho Diagnostics, Raritan, NJ) detected by FACS analysis.¹⁵

For certain studies HL-60 cells were incubated for four days with and without 5 mmol/L α -difluoromethyl ornithine (DFMO) (Merrill Dow, Cincinnati), which arrests cellular proliferation but does not induce maturation.¹⁶ For these studies cells were placed into fresh ITS media with and without DFMO every 24 hours as described previously.¹⁶

Measurement of IMP dehydrogenase in cell extracts. Cell pellets (containing 5×10^6 to 5×10^7 cells) were disrupted by sonication in 1.0 mL Tris buffer (0.1 mol/L Tris-HCl, 0.02 mol/L KCl, 1.0 mmol/L dithiothreitol, pH 8.1) over ice. Sonicates were then centrifuged at $12,000 \times g$, and IMPD was extracted from the supernatant by acid precipitation with 0.5 mL of 1.0 mol/L sodium acetate, pH 5.0, added to 1.0 mL of supernatant. After a two-minute repeat centrifugation at $12,000 \times g$, the pelleted precipitate was redissolved in 500 μ L Tris buffer, pH 8.1. Insoluble materials were eliminated by recentrifugation and the supernatant extract used as an enzyme source. Total protein concentrations in cell sonicates and in cell extracts were determined by the Bio-Rad colorimetric method (Bio-Rad Laboratories, Richmond, CA).

IMPD activity in cellular extracts was then measured by a radiometric assay, modified from methods previously reported by Cooney et al.¹⁷ This assay is based upon the recovery of tritiated water produced during the IMPD-mediated generation of XMP from [2-³H] IMP. For the assay 100- μ L aliquots of cell extracts were incubated at 37 °C with 50 μ L of allopurinol (20 μ mol/L); 50 μ L of 0.1 mol/L uridine (Sigma), and 5 μ L of [2-³H] IMP [200 μ Ci/mL; 225 nmol/mL; prepared from [2-³H] hypoxanthine as described previously¹⁷] with NAD (Sigma; final concentration = 70 μ mol/L) in a total reaction volume of 205 μ L. The IMPD reaction was terminated after incubation at 23 °C for zero to 120 minutes by applying 100- μ L aliquots of the reaction mixtures to replicate 6 $\times$ 30 mm Dowex-1-C1⁻ columns (Bio-Rad), followed by elution of the columns with 1.9 mL distilled H₂O and collection of eluants in scintillation vials with 20 mL Hydrofluor (National Diagnostics, Summerville, NJ). In this assay, anion exchange resin columns, which absorb unreacted [2-³H] IMP while ³H₂O is eluted, were used instead of saturated KOH solution as originally described¹⁷ to separate the reaction products. This modification improved the reproducibility and efficiency of the assay in our hands; nonetheless, results were similar with both versions of the radiometric assay. The radioactivity of released tritium was measured in a beta-scintillation counter and converted to pmol of IMP metabolized per minute. Enzyme activity was expressed both in relationship to the number of cells extracted and to total extracted protein added to the reaction mixture.

The specificity of the dehydrogenation reaction of IMP to XMP was confirmed by reverse phase and ion exchange chromatography,⁸ and by comparing reaction conditions with and without added NAD. Breakdown of the radiolabeled IMP to inosine by nonspecific phosphatase activity was minimal (5% of total radioactivity) to undetectable.

Measurement of intracellular purine ribonucleotide concentrations. Purine ribonucleotides in perchlorate extracts of 2×10^7 cell pellets were analyzed by reverse phase HPLC using an anion exchange, microparticulate column (Partasil-10 SAX; Whatman, Clifton, NJ) as described previously.⁸ Ribonucleotide (GTP and

ATP) concentrations (nmol/ 10^7 cells) were derived from chromatographic peaks detected by UV absorbance at 254 nm, which were related to standards chromatographed at known concentrations.

Purification of normal peripheral blood neutrophils and monocytes. Neutrophils and monocytes were separated from venous blood samples (50 to 100 mL) obtained from normal volunteers. Neutrophils (>95% purity) were isolated by dextran sedimentation of whole blood followed by centrifugation on Hypaque-Ficoll density gradients (Ficoll-Paque; Pharmacia, Piscataway, NJ) and hypotonic lysis of residual erythrocytes.¹⁸ Blood monocytes (>90% purity) were isolated from the buoyant mononuclear cells, recovered from Hypaque-Ficoll gradient-separated blood, by counter-flow elutriation as described previously.¹⁹

Presentation and statistical analysis of results. Unless otherwise noted, results are expressed as mean values $\pm$ the standard error of the mean for replicate measurements. *P* values for the statistical significance of differences were determined by the Student's *t* test.

RESULTS

IMP dehydrogenase activity in human myeloid leukemia cells lines and in normal blood leukocytes. IMPD activity was readily detected in extracts of HL-60 cells harvested from maintenance culture. Dehydrogenation of IMP by extracts of 2×10^7 HL-60 cells was linear during the first 20 minutes of incubation with radiolabeled substrate but slowed thereafter. Therefore attention was given to using incubation times and sample dilutions that would conform to linear reaction conditions. Under such conditions IMPD activity was directly related both to the numbers of cells from which extracts were prepared (within a range of 1.0 to 3.0×10^7 cells) and to the protein content of cell extracts (within a range of 0.2 to 3.0 mg cell protein).

Consistent with previous reports that leukemic blast cells have higher levels of IMPD than do mature leukocytes,¹² both HL-60 and RFD2-25 cells were found to have substantially higher levels of IMPD activity than did purified, normal blood neutrophils or monocytes. Levels of IMPD activity expressed as pmol IMP metabolized/ 10^7 cells/minute ($\pm$ SEM, $n = 6$) were 5.7 ± 0.5 and 5.2 ± 0.2 for HL-60 and RFD2-25 cells respectively, compared with 1.1 ± 0.4 and 1.4 ± 0.4 for neutrophils and monocytes; IMPD levels expressed as pmol IMP metabolized/mg cell protein/min ($\pm$ SEM, $n = 6$) were 27.6 ± 2.2 and 20.6 ± 0.8 for HL-60 and RFD2-25 cells, compared with 4.5 ± 1.7 and 7.5 ± 2.3 for neutrophils and monocytes.

IMP-dehydrogenase activity in myeloid leukemia cells during induced maturation. Substantial decreases in IMPD activity were observed in HL-60 cells by three hours of incubation with agents that induced maturation of the cells (Figs 1A and 1B); these decreases in IMPD activity were apparent both when enzyme activity was expressed in relationship to cell numbers and when expressed in relationship to milligrams of extracted protein assayed. The most rapid decline in IMPD activity was observed in cells treated with tiazofurin; in these cells IMPD levels were decreased by more than 75% within six hours and remained low thereafter (The slight rise in IMPD levels between six and 24 hours apparent in Figs 1A and 1B is not statistically significant). The decline in IMPD activity in cells treated with retinoic acid and dimethylformamide was somewhat more gradual

Fig 1. Rapidly declining IMP dehydrogenase activity in HL-60 cells during incubation with inducing agents. IMPD activity is expressed both in terms of milligrams of cell protein extracted (A) and in terms of number of cells extracted (B). Results represent mean values $\pm$ SEM from six replicate studies. Solid circles: control cells not exposed to inducing agents; open circles: cells incubated with retinoic acid (10^{-6} mol/L); open triangles: cells incubated with dimethylformamide (60 mmol/L); open squares: cells incubated with tiazofurin (10^{-6} mol/L).

than in tiazofurin-treated cells but was fully established by 12 hours of incubation with the inducing agents. In all cases substantially decreased IMPD levels were detectable at least 12 to 18 hours before cellular maturation was apparent either by measurement of phorbol diester-stimulated NBT reduction, by measurement of the myeloid surface antigen OKM1 (Figs 2B and 2C), or by measurement of phagocytic activity (data not shown).

Changes in IMPD levels during induced maturation of HL-60 cells were not related temporally to changes in cellular proliferation. IMPD levels fell markedly during the first 12 hours of induction (Figs 1A and 1B) before significant changes in the cell growth rate ($P < 0.05$) were observed (Fig 2A). Furthermore, DFMO, which markedly inhibits HL-60 cell growth but does not induce maturation,¹⁶ was not found to cause either decreased IMPD levels in the cells or changes in intracellular guanine ribonucleotide concentrations, unlike the maturation inducers, retinoic acid and dimethylformamide (Table 1).

Decreased IMPD levels in association with induced myeloid maturation were also observed in another human leukemia cell line, RFD2-25. This line was isolated from a patient with acute myelogenous leukemia, FAB class M1 (see "Materials and Methods" section) and is unrelated to the HL-60 line. As in HL-60 cells, IMPD activity in RFD2-25 cells was decreased by more than 50% within six hours of incubation with retinoic acid, dimethylformamide, or tiazofurin and remained at these diminished levels during

Fig 2. (A) Increase in cell numbers during 72-hour culture for HL-60 cells incubated without inducing agents (closed circles), with retinoic acid, 10^{-6} mol/L (open circles), with dimethyl-formamide, 60 mmol/L (open triangles), or with tiazofurin, 10^{-6} mol/L (open squares). Results represent mean values $\pm$ SEM from four replicate studies; data points marked with an asterisk (*) are significantly different from control data for cells incubated without inducing agents ($P < 0.05$). (B and C) Acquisition of functional maturity by HL-60 cells incubated with inducing agents: (B) NBT reduction by 10^6 cells stimulated with phorbol myristate acetate (100 ng/mL) for 30 minutes (NBT reduction is expressed as Δ OD units₅₁₅/30 minutes); (C) Percent of cells expressing the OKM1 antigen. Cross-hatched horizontal bars represent limits of mean values $\pm$ 2 SD from six separate studies for control, uninduced cells examined at 0, 12, 24, and 48 hours of incubation. Open circles: cells incubated with retinoic acid (10^{-6} mol/L); open triangles: cells incubated with dimethylformamide (60 mmol/L); open squares: cells incubated with tiazofurin (10^{-6} mol/L). Results are mean values from triplicate measurements.

subsequent culture. A separate strain of RDFS2, RDFS2-4, which was segregated from the parent RDFS2 isolate following the eighth passage of this line by a limiting dilution cloning technique, was found to be resistant to maturation induction. These cells showed no decrease in IMPD activity in response to retinoic acid or dimethylformamide (Table 2), which were also ineffective in inducing these cells to mature. RDFS2-4 cells showed only a modest decline in IMPD activity ($<30\%$) when incubated with the IMPD inhibitor, tiazofurin (10^{-6} mmol/L), which was correspondingly relatively ineffective in inducing maturation, although a modest degree of induced maturation could be detected (Table 2).

DISCUSSION

Inosine monophosphate dehydrogenase (IMPD) catalyzes the first step unique to guanylate biosynthesis from the

central purine intermediate, IMP, whereby IMP is converted to XMP. This irreversible reaction is known to be subject to both negative and positive feedback controls and to be rate limiting for the formation of guanine ribonucleotides in cells under physiologic conditions.^{20,21} We investigated the activity of this enzyme in two human myeloid leukemia cell lines, HL-60 and RDFS2-25, and in normal peripheral blood neutrophils and monocytes using a radiometric assay. We found both myeloid cell lines to have substantially higher levels of IMPD than purified normal blood neutrophils or monocytes. In addition, we observed that induced maturation of the leukemic cell lines is associated with a reduction in the activity of IMPD toward those levels observed in normal, terminally differentiated neutrophils and monocytes. Moreover, decreased IMPD activity was found to be a very early feature of induced maturation. A significant decline in

Table 1. IMP Dehydrogenase Levels in HL-60 Cells With and Without Induced Maturation

Incubation Conditions	IMPD Activity*	Intracellular [GTP] (nmol/ 10^7 cells)†	Cellular Proliferation (Percent increase in cell concentration by four days)‡	Myeloid Maturation (NBT reduction by cells after four days culture)§

IMPD activity was evident by three to six hours of incubation of HL-60 and RD62-25 cells with inducing agents and preceded the functional and antigenic maturation of these cells by at least 12 to 18 hours.

Diminished IMPD activity in HL-60 and RD62 cells treated with tiazofurin was not anticipated, since this agent is known to inhibit IMPD directly and selectively.^{22,23} However, the mechanism by which IMPD is down-regulated in these cells when exposed to retinoic acid or dimethylformamide is unclear. Nonetheless, these findings are consistent with our previously reported observation that guanine ribonucleotide biosynthesis from IMP is reduced in HL-60 cells during induced maturation in part because of an apparent block at the IMPD-mediated step.⁸

Several additional observations in our present studies lend further weight to the conclusion that reduced levels of IMPD activity and myeloid cell maturation are related. Decreased IMPD levels were not observed in a strain of RD62 cells that is resistant to maturation-induction when these cells (RD62-4) were incubated with the inducing agents retinoic acid and dimethylformamide. Moreover, changes in IMPD activity observed with cellular maturation could be dissociated from altered rates of cell division. Not only did IMPD levels fall in the myeloid cell lines before the decline in cell growth rate that accompanies induced maturation, but IMPD levels did not fall in cells exposed to DFMO, which blocks cellular proliferation but does not induce maturation.¹⁶

Becker and Lohr¹² have reported previously that the circulating blasts of patients with acute myelogenous leukemia have high levels of IMPD activity compared with those of normal blood leukocytes recovered from healthy subjects. Although our methods for measuring IMPD differ from those used in these earlier studies, our results with HL-60 and RD62 cells are quantitatively similar to those reported for freshly isolated leukemic blast cells.¹²

A relationship between the activity of IMPD and neoplastic transformation has been suggested by Jackson et al.¹⁰ These investigators found that rat hepatoma cells had substantially higher levels of IMPD activity than did normal liver cells. IMPD activity in hepatoma cells was also greater than that in normal regenerating liver tissue with similar cell

growth rates.^{10,11} Although we were unable to compare the IMPD levels of leukemic cells with those of a comparably homogenous preparation of normal myeloid progenitor cells, our studies support the idea that a high level of IMPD activity in cells is a biochemical marker of cellular immaturity. Not only do HL-60 and RD62 cells have high levels of IMPD compared with their normal, terminally differentiated blood cell counterparts, but they also express diminished IMPD activity in association with induced maturation, whereby the block in terminal differentiation characteristic of these neoplastic cells in maintenance culture is circumvented or partially removed. At the same time it is important to point out that the induction conditions examined in our studies are among those that promote a form of cellular maturation reminiscent of neutrophil differentiation.⁵⁻⁷ We did not examine induction conditions associated with cellular maturation to macrophage-like^{24,25} or eosinophil-like cells,²⁶ and our results may not necessarily apply to such conditions.

While diminished IMPD activity may be simply a biochemical consequence of cellular maturation, there is reason to believe that the activity of this enzyme may have a role in regulating the maturation process by controlling intracellular supplies of guanine ribonucleotides. Several lines of evidence support this latter possibility. First, we have shown previously that IMPD inhibitors are potent inducers of maturation in human myeloid cell lines.^{8,9} Second, we have shown in more recent studies²⁷ that the maturation-inducing effects of IMPD inhibitors on HL-60 cells can be blocked by preventing the depletion of guanine ribonucleotide pools that ordinarily results from IMPD inhibition; this is accomplished by incubating cells with guanosine or guanine to provide the cells with a substrate for guanylate synthesis by direct salvage, bypassing the synthetic pathway from IMP.

In cell-free extracts, IMPD is known to be subject to negative feedback inhibition by XMP and GMP and to require NAD as a cofactor.^{20,21} These characteristics of the enzyme have been used as the basis for designing nucleoside analogues that function as selective IMPD inhibitors, such as tiazofurin.²² In intact cells, however, this enzyme may be subject to a variety of additional controls at the level of enzyme synthesis, degradation, or posttranslational modification, and it is possible that the changes observed in IMPD

activity in cells treated with retinoic acid or dimethylformamide reflect such control mechanisms. In any case, our studies suggest that such controls of IMPD activity deserve further investigation, since they may be relevant both to normal and to disordered regulation of myeloid cell maturation. Our studies also support the suggestion of others^{11,23} that IMPD is an appropriate target for the design of new chemotherapies that may have selective antineoplastic effects.

Recombinant Tumor Necrosis Factor Causes Activation of Human Granulocytes

By James W. Larrick, Delores Graham, Karen Toy, Leo S. Lin, George Senyk, and Brian M. Fendly

We have tested the hypothesis that tumor necrosis factor (TNF), by binding to and activating granulocytes, may contribute to the pathogenesis of gram-negative sepsis and the adult respiratory distress syndrome (ARDS). Buffy coat granulocytes incubated with as little as 0.5 ng/mL of recombinant TNF (rTNF) showed a dose-related increase in nitroblue tetrazolium dye reduction, in granulocyte polarization, in superoxide anion release, and in visually apparent aggregation. Purified lipopolysaccharide (1 μ g/mL) caused polymorphonuclear (PMN) aggregation and activation that

was neutralized by polymyxin B. The release of superoxide was augmented by preincubation of the PMNs with γ -interferon. The effect of TNF was neutralized by TNF-specific murine monoclonal antibodies but not by polymyxin B. Scatchard analysis of ^{125} I-rTNF binding to granulocytes revealed about 1,200 receptors per cell with a K_d of 4.9×10^{-10} mol/L. These results suggest that the release of TNF by mononuclear phagocytes contributes to granulocyte activation and aggregation during inflammation.

© 1987 by Grune & Stratton, Inc.

INFLAMMATION is characterized by the rapid accumulation of granulocytes and monocytes at sites of tissue injury. These cells participate in the destruction and rapid removal of foreign antigens and damaged tissue. A number of agents have been found to cause activation and chemotaxis of phagocytes including complement fragments,^{1,2} products involved in the kinin and coagulation pathways,^{3,4} collagen,⁵ tissue breakdown products, and arachidonic acid metabolites,⁶⁻⁹ in particular, leukotriene B₄,¹⁰ as well as synthetic peptides related to bacterial-derived products.^{11,12} Most of these substances are generated during an inflammatory response.

During the course of work in our laboratory on the pathogenesis of endotoxemia, we found that tumor necrosis factor (TNF) was released by lipopolysaccharide (LPS) stimulation of macrophages. First described by Carswell et al¹³ in the serum of mice injected with bacillus Calmette-Guerin vaccine and endotoxin, TNF was noted principally for its cytolytic effects on tumor cells. Work by Beutler and coworkers¹⁴⁻¹⁶ has since suggested that TNF might be an important mediator in the response to injury by mobilizing the host energy reserves. Although C5a is known to be a major cause of activation and aggregation of granulocytes, we postulate that TNF may also contribute to the granulocyte response. In the present studies we show that granulocytes have specific high-affinity receptors for TNF and that low concentrations of TNF cause aggregation and activation of granulocytes. These effects can be blocked by monoclonal antibodies neutralizing TNF.

MATERIALS AND METHODS

Reagents. *Escherichia coli* 0111:B4 LPS was purchased from LIST Biologicals (Campbell, CA). Nitroblue tetrazolium salt (NBT), polymyxin B, formylmethionylleucylphenylalanine

(FMLP), cytochalasin B, superoxide dismutase (SOD), dexamethasone, and ferricytochrome c (horse heart VI) were purchased from Sigma Chemical Co (St Louis).

Cold C5a was kindly provided by Dr Steven Kunkel, University of Michigan, Ann Arbor, MI. Recombinant human TNF (rTNF),¹ interleukin 2, and β -interferon were provided by the Process Group of Cetus Corp, Emeryville, CA. Purified human γ -interferon was obtained from Meloy Laboratories, Springfield, VA.

Antibodies. Rabbit and monoclonal anti-TNF antibodies were generated as previously described.¹⁸

L929 cytotoxicity assay. L929 cells were the kind gift of Dr Lloyd Old, Memorial Sloan-Kettering Cancer Center. Details of the assay for TNF and neutralization by mouse serum and mouse monoclonals are as described.¹⁸

Neutrophil polarization. Polarization of human polymorphonuclear (PMN) leukocytes was performed as described^{19,20} with minor modifications. PMNs were isolated from fresh heparinized blood by dextran sedimentation followed by Ficoll-Hypaque gradient centrifugation. The PMNs were adjusted to 1×10^6 cells/mL of Hanks' buffered saline solution (HBSS), and 0.9 mL was added to each of duplicate tubes (12 $\times$ 75 mm polypropylene) containing 0.1 mL of stimulant or HBSS. The samples were incubated 15 minutes in a 37 °C shaking waterbath. To end the reaction, 1 mL of ice-cold, 0.1 mol/L phosphate-buffered formaldehyde (10% vol/vol), pH 7.2, was added to each tube. Cells were kept cold (4 °C) until they were examined by phase microscopy. Tubes were coded and scored blindly for gross morphological changes indicating polarization. PMNs, round when unstimulated, were considered to exhibit polarization when their shape appeared elongated, often with distinct uropods. The percentage of cells polarized was determined by counting 200 cells per tube.

Ferricytochrome c reduction assay. Superoxide anion production was measured by the ferricytochrome c reduction method.²¹ PMNs (1×10^6 cells) were suspended in HBSS (without phenol red), pH 7.2, in 12 $\times$ 75-mm tubes containing stimulant and ferricytochrome c (80 μ mol/L final concentration) for a final volume of 1 mL. In some experiments PMNs were pretreated with 5 μ g/mL cytochalasin B for five minutes at 37 °C prior to stimulation. Controls containing SOD also were run in parallel. Tubes were incubated at 37 °C for 15 minutes. The reaction was stopped by centrifuging the suspension for ten minutes at 1,200 rpm at 4 °C. Absorbance of the supernatants was then determined using a spectrophotometer at 550 nm. The 550-nm optical density values were converted to nanomoles of reduced cytochrome c using the extinction coefficient 21.0×10^3 (mol/L)⁻¹ cm⁻¹ and expressed as nmoles/10⁶ PMNs/15 minutes.

NBT reduction assay. The buffy coat blood fraction (from a blood bank in a volume of 20 to 30 mL from 1 unit of blood) served as the source of granulocytes. Assays were performed in small, plastic cryogenic vials (Corning Glass Works, Corning, NY) in a volume of 0.5 mL. To 0.25 mL of buffy coat blood was added 0.25 mL of NBT

dye (Sigma Chemical Co) at 2 mg/mL in saline. Additional ingredients were added in small volumes to achieve the desired concentration, and vials were incubated for 30 minutes at 37 °C. When assaying the efficacy of antibodies, antigen and antibody were preincubated in small volumes (5 to 25 μ L) in 96-well round-bottom Costar plates under conditions of high humidity for 30 minutes at 37 °C before being transferred to assay vials. Following incubation, thin coverslip blood smears were made, air-dried, and stained with Wright-Giemsa stain (Camco Quick Stain, Cambridge Chemical Products, Ft Lauderdale, FL). Smears were then examined under oil immersion and scored for the percentage of NBT-positive PMNs, ie, those containing black deposits of reduced NBT dye in their cytoplasm. The baseline NBT reduction, ie, with no stimulus, was less than 1% in all experiments. The biochemical basis of this assay has been defined.²²

TNF binding assay. TNF was labeled to a specific activity of 20 μ Ci/ μ g of protein using the iodogen method (Pierce Chemical Co, Rockford, IL). Binding assays were performed on 5×10^6 cells using various concentrations of labeled TNF. Binding assays were carried out for four hours at 4 °C. Cells were separated from unbound ¹²⁵I-TNF by three washes in 2% sucrose in phosphate-buffered saline. In all experiments, a 100-fold excess TNF was added, and the nonspecific ¹²⁵I-TNF binding was subtracted.

RESULTS

To rule out the possibility that TNF was directly cytotoxic to granulocytes, we incubated PMNs in HBSS with 10 and 1 μ g/mL of rTNF, with FMLP (10^{-6} mol/L), and with no additives. Cell viability was observed using both trypan blue dye exclusion and ethidium bromide/acridine orange staining. No differences in viability were observed among the four cell populations over a period of 22 hours (data not shown).

Activation of human granulocytes by rTNF. Figure 1 shows that rTNF induces a dose-dependent increase in NBT dye reduction by human granulocytes. A concentration of rTNF as low as 100 pmol/L (1.7 ng/mL = 100 pmol/L) produces granulocyte activation well above the background. No-stimulus controls were less than 1% in all NBT studies (data not shown). Polymyxin B, which blocks LPS-induced

Fig 1. Dose response of rTNF-induced granulocyte NBT dye reduction. Note that the LPS-induced NBT reduction is blocked by polymyxin B (5 mg/mL); the effect of rTNF is not. The assay was read after 30 minutes' incubation. The no-stimulus control values were <1% positive.

Fig 2. Kinetics of the activation process. The kinetics of FMLP- and rTNF-induced NBT dye reduction are identical. Full induction of NBT dye reduction begins to plateau at 15 minutes. Concentrations of 50 ng/mL rTNF and 1.0 μ mol/L FMLP were used for these studies. The no-stimulus control values were <1%.

NBT dye reduction,^{23,24} did not block the rTNF-induced activation of granulocytes. Interestingly, when concentrations of LPS (2 μ g/mL) and rTNF (100 ng/mL), both of which induced maximal granulocyte NBT dye reduction alone, were added together to the cells, no additional increase in the number of positive cells was observed (data not shown). Aggregation of PMNs was visually apparent at doses of rTNF above 100 ng/mL. No stimulation of NBT reduction with rTNF or LPS was observed in the presence of 1 mmol/L *N*-ethylmaleimide, which suggests that a superoxide-generating oxidase was reducing the NBT.

Figure 2 shows the kinetics of the activation process comparing FMLP (1.0 μ mol/L) and TNF (50 ng/mL). Both substances induce rapid activation, with a plateau beginning after 15 minutes.

rTNF also produces a dose-dependent increase in human granulocyte polarization similar to the response seen with C5a, a known chemotactic factor (Table 1). PMN polarization induced by rTNF was more pronounced than that produced by LPS. Furthermore, the activation induced by rTNF was not reduced by the addition of polymyxin B (Table 2).

To determine whether rTNF contributed to the respiratory burst observed during the activation of PMNs, measurements of the superoxide anion were made by the ferricytochrome c reduction method. Table 3 shows that rTNF caused

Table 1. rTNF-Induced Polarization of PMNs

a two- to threefold increase in the release of superoxide anion. Furthermore, the stimulation was augmented by preincubation of the PMNs with 100 units of γ -interferon. Note that these studies were performed in the absence of cytochalasin B, which is frequently used to augment O_2^- release. When cytochalasin B is added to the cells prior to stimulation, there is a modest increase in TNF stimulation at the higher concentrations (Table 4). Cells stimulated by FMLP in the presence of cytochalasin B released up to 20-fold more O_2^- .

Neutralization of rTNF activation of granulocytes by antibodies. Both rabbit (Fig 3) and mouse (Fig 4) antisera, which neutralized the in vitro cytotoxicity of rTNF, blocked rTNF-induced NBT dye reduction by granulocytes. In addition, a series of murine anti-TNF monoclonal antibodies was tested. These monoclonals were shown to neutralize rTNF-induced mouse L cell cytotoxicity¹⁸ as well as rTNF-induced granulocyte NBT dye reduction (Fig 4).

Binding of rTNF to human granulocytes. Human granulocytes demonstrated rapid saturable binding of ¹²⁵I-labeled rTNF. Scatchard analysis revealed a low number (1,174 sites/cell) of high-affinity ($K_d = 5 \times 10^{-10}$ mol/L) receptors on these cells (Fig 5). This binding was inhibited by a 100-fold molar excess of cold rTNF but not by a 100-fold molar excess of human C5a, recombinant interleukin 2, or β -interferon (data not shown).

DISCUSSION

These studies demonstrate that purified human rTNF binds specifically to high-affinity receptors on PMN leuko-

Table 4. rTNF-Induced Generation of Superoxide Anion in the Presence of Cytochalasin B

	Control	Cytochalasin B (5 µg/mL)*
FMLP, 10^{-7} mol/L	1.1 ± 0.5 †	26.7 ± 3.1
TNF, 1 µg/mL	2.8 ± 0.7	6.3 ± 0.7
100 ng/mL	3.3 ± 0.8	4.3 ± 0.6
10 ng/mL	2.3 ± 0.4	2.4 ± 0.4

The values are the mean and SE of six experiments without cytochalasin B and three experiments with cytochalasin B.

*Cells were preincubated for ten minutes 37 °C with cytochalasin B prior to the addition of stimulants.

†Values are expressed in $nm\ O_2^-/10^6$ PMNs/15 min minus the cell control values ($\pm$ SE).

cytes and that this binding leads to a dose-dependent increase in the activation of these granulocytes. The concentration of rTNF required to elicit PMN cell polarization and the reduction of NBT dye is as low as 100 pmol/L, which compares favorably with the receptor affinity measured on these cells and on other cells tested in our labs and by other investigators.²⁵⁻²⁷ The concentrations of rTNF required to induce visually apparent aggregation and production of significant amounts of superoxide anion are up to tenfold higher. A number of laboratories have investigated this dissociation of membrane polarization and the oxidative burst.²⁸⁻³⁰ For example, Sklar et al³¹ showed that the time of receptor occupation by FMLP determined the relative membrane potential changes and the amount of superoxide generated. Longer receptor occupancy or a higher percentage of receptor occupation was required for the generation of O_2^- . γ -Interferon modestly sensitizes neutrophils to the effects of low concentrations of TNF. Synergism has been shown by workers studying TNF-induced granulocyte-mediated cytotoxicity³² and TNF-mediated tumor killing.³³ Studies by two groups^{34,35} have recently shown that γ -interferon modestly enhances the expression of TNF receptors. The low concentrations of TNF required to stimulate the respiratory burst are within the range commonly found in cultures of stimulated macrophages (J.W. Larrick, unpublished data) and are probably physiologically relevant at the sites of inflammation. Although researchers have commonly used cytochalasin B to increase the detection of released O_2^- by FMLP-stimulated PMNs, our studies show that this agent had only

Table 3. rTNF-Induced Superoxide Production by PMNs

PMNs at a 10^6 /mL concentration were preincubated at 37 °C for 20 minutes with either HBSS or 100 U/mL γ -interferon, then tested for their response to rTNF. The data are presented as nmol/ 10^6 PMN/15 min. There was no cytochalasin B preincubation in these experiments.

*Mean $\pm$ SE of six experiments.

Fig 3. Neutralization of rTNF-induced NBT dye reduction by rabbit anti-TNF antiserum. Following preincubation (30 minutes) with rTNF (final assay concentrations are shown in the Fig) in small equal volumes, the α TNF serum was at a 1:20 dilution during the 30-minute assay. The no-stimulus control values were <1% positive.

Fig 4. Neutralization of rTNF-induced NBT dye reduction by mouse anti-TNF antiserum and anti-TNF monoclonal antibodies. Following preincubation (30 minutes) with rTNF (final assay concentrations of 50 ng/mL) in small equal volumes, monoclonals were in a 4 mol/L excess to rTNF and mouse anti-TNF serum at 1:20 dilution during the 30-minute assay. Normal mouse serum and the control IgG, monoclonal do not neutralize the cytotoxic effect of rTNF in the L929 assay. Anti-TNF mouse serum and the three monoclonals all neutralize rTNF in the L929 assay. The no-stimulus control values were <1%.

modest effects on the O_2^- released by TNF-stimulated PMNs.

Our studies show that TNF binds to a low number of high-affinity sites on PMN leukocytes. This binding is both specific and saturable. Similar dissociation constants and numbers of TNF receptors have been reported by others²⁵ using various cell lines. Because TNF is known to bind to both sensitive and insensitive cell lines, it will be important to better understand how receptor occupancy triggers normal cells to respond and certain neoplastic cell lines to die. The 5-lipoxygenase pathway has been implicated in receptor-response coupling of PMNs,³⁶⁻³⁸ but to date our studies with the arachidonate inhibitors ETYA, BW755, indomethacin, and nordihydroguaiaretic acid (NDGA) have given little or no inhibition of TNF-induced activation (data not shown). Studies of other second-messenger pathways are in progress.

Our work suggests that TNF is a member of a growing list of inflammatory mediators that bind to and cause activation of granulocytes. It also provides evidence that mononuclear

Fig 5. Scatchard analysis of ^{125}I -rTNF binding to human granulocytes. Granulocytes (5×10^6) were incubated with labeled rTNF for 14 hours at 4°C. Counts bound in the presence of 100-fold excess cold rTNF were subtracted from counts bound to give the specific rTNF bindings.

phagocytes may stimulate granulocytes via TNF during inflammation. Other groups have recently shown that TNF stimulates binding to endothelial cells³⁹ as well as granulocyte phagocytosis.^{32,40} Clearly, there is a complex interplay of these recently cloned cytokines in the inflammatory response. The recent work of Beutler et al¹⁵ is interesting in this regard. These workers showed that in a murine model of LPS toxicity the lethal effect of endotoxin can be reduced by rabbit antimurine TNF (cachectin) antibodies. If TNF is a major mediator of endotoxemia, its effects on granulocytes and endothelial cells may contribute to the pathogenesis of septic shock and the adult respiratory distress syndrome (ARDS). To date, activation of the alternate pathway of complement with the release of C5a has been thought to be the major stimulant of granulocyte aggregation in this context.⁴¹⁻⁴³ The present studies show that TNF must be included with mediators such as LTB₄, platelet-activating factor, and C5a, which contribute to the aggregation of granulocytes with the subsequent compromise of pulmonary function in gram-negative sepsis and ARDS. Whether the effect of rTNF on PMNs observed in these studies contributes to its antitumor effect or to its toxicity is currently under investigation. From a therapeutic standpoint, the inhibition of the inflammatory effects of TNF may be as important as its direct antitumor effects.

Studies of a Mechanism Inhibiting the Initiation of the Extrinsic Pathway of Coagulation

By L. Vijaya Mohan Rao and Samuel I. Rapaport

We have extended earlier studies (Blood 66:204, 1985) of a mechanism of inhibition of factor VIIa/tissue factor activity that requires a plasma component (called herein extrinsic pathway inhibitor or EPI) and factor Xa. An activated peptide release assay using ^3H -factor IX as a substrate was used to evaluate inhibition. Increasing the tissue factor concentration from 20% to 40% (vol/vol) overcame the inhibitory mechanism in normal plasma but not in factor VII-deficient plasma supplemented with a low concentration of factor VII. A second wave of factor IX activation obtained by a second addition of tissue factor to plasma with a normal factor VII concentration was almost abolished by supplementing the reaction mixture with additional EPI and factor X. Factor Xa's active site was

necessary for factor Xa's contribution to inhibition, but preliminary incubation of factor Xa with EPI in the absence of factor VIIa/tissue factor complex or of factor VIIa/tissue factor complex in the absence of EPI did not replace the need for the simultaneous presence of factor Xa, factor VIIa/tissue factor, calcium, and EPI in an inhibitory reaction mixture. Inhibition of factor VIIa/tissue factor was reversible; both tissue factor and factor VIIa activity could be recovered from a dissociated, inhibited factor VIIa/tissue factor complex. EPI appeared to bind to a factor VIIa/tissue factor complex formed in the presence of factor Xa but not to a factor VIIa/tissue factor complex formed in the absence of factor Xa.

KKNOWN INHIBITORY mechanisms regulating blood coagulation include neutralization of the serine protease enzymes—factors IXa, Xa, and thrombin—by the protease inhibitors antithrombin III and heparin cofactor II and inhibition of the cofactors—factor VIIIa and Va—by activated protein C. These inhibitory reactions modulate the intermediate and late steps of blood coagulation. Little is yet known about inhibitory mechanisms that modulate the initiation of blood coagulation following exposure of blood to tissue factor (ie, initiation of coagulation via the extrinsic pathway). However, it has been known since 1947 that a preliminary incubation of tissue factor with serum would abolish its otherwise lethal effect after intravenous injection into mice.^{1,2} Moreover, it was shown in the early 1950s that the coagulant activity formed after the addition of tissue factor to serum in vitro diminished rapidly on further incubation.³

In a recent report from this laboratory, a plasma-inhibitory material was described that inhibits factor VIIa/tissue factor activity only when factor X is also present in reaction mixtures.⁴ We report herein the results of experiments carried out to explore further the mechanism of this inhibition.

MATERIALS AND METHODS

Reagents. Hereditary clotting factor-deficient plasmas were obtained from George King Bio-Medical, Overland Park, KS. Rabbit brain cephalin was obtained from Sigma Chemical Co (St Louis). $\text{Na}^3[\text{H}]$ borohydride from Amersham Corp (Arlington Heights, IL), Sephacryl S-200 and CNBr-activated Sepharose 4B from Pharmacia Fine Chemicals (Piscataway, NJ), diethyl aminoethyl Affi-gel blue and all electrophoretic reagents from Bio-Rad Laboratories (Richmond, CA). Unless otherwise specified, the buffer used to dilute reagents contained 0.05 mol/L Tris-HCl, 0.15 mol/L NaCl, pH 7.5, and 1 mg/mL bovine serum albumin (TBS/BSA).

Plasmas. Normal pooled plasma and barium-absorbed plasma were prepared as described earlier.⁴ For some experiments, factor VII-deficient plasma and barium-absorbed plasma were passed through an anti-factor VII column, and factor X-deficient plasma was passed through an anti-factor X column to remove traces of factor VII and factor X from these plasmas, respectively.

Tissue factor. Crude tissue factor preparations were saline extracts of human brain. The standard reagent, prepared as

described earlier,⁴ clotted normal plasma in 13 seconds. A particulate tissue factor reagent, with activity that could be pelleted by centrifugation at 12,000 g for ten minutes, was prepared as described by Bajaj et al.⁵ This tissue factor clotted normal plasma in 22 seconds. A purified tissue factor reagent was used for selected confirmatory experiments. It was prepared by reconstituting purified tissue factor apoprotein, isolated by a modified factor VII affinity technique to be described elsewhere, with a phospholipid mixture containing phosphatidyl ethanolamine, phosphatidyl choline, and phosphatidyl serine (1:1:0.3). This reconstituted, purified tissue factor was diluted in buffer to a concentration that clotted normal plasma in 18 seconds.

Purified human clotting factors. Human factors VII,⁶ IX, and X⁷ were purified to homogeneity by methods described earlier from this laboratory. Purified clotting factor concentrations were determined spectroscopically at A (absorbance) 280 nm using an $E_{\text{cm}}^{1\%}$ (extinction coefficient) of 13.9 for factor VII,⁸ 13.2 for factor IX,⁹ and 11.6 for factors X and Xa.⁹

Factor Xa. This was prepared by incubating purified factor X with insolubilized Russell's viper venom in the presence of calcium as described earlier.⁷ It was stored at -20°C in 50% vol/vol glycerol and diluted to the desired concentration in buffer just before use. The factor Xa had a specific activity of approximately 1,300 U/mg as measured in a one-stage factor Xa assay.¹⁰ It contained 5% to 10% residual zymogen factor X as judged by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis.

Factor VIIa. Factor VIIa was prepared just before use by incubating factor VII at a concentration of either 50 $\mu\text{g/mL}$ or 2.5 $\mu\text{g/mL}$ with factor Xa in a 50:1 ratio (wt/wt) for 15 minutes at 37 °C in the presence of 0.42 mmol/L cephalin and 5 mmol/L calcium. In some experiments the factor VIIa preparation was incubated with antibodies to factor X to neutralize the factor Xa activity.

Antibodies to factor VII. Antibodies were raised to purified human factor VII in a goat. The antiserum was adsorbed with barium sulfate (100 mg/mL) and heated to 56 °C for 20 minutes. At a 1,600-fold dilution this antiserum neutralized 50% of the activity of factor VII in normal plasma. It gave a single precipitation line on immunodiffusion against purified factor VII but not against prothrombin, factor X, factor IX, protein C, or protein S. An immunoglobulin fraction was prepared by precipitation at a 45% ammonium sulfate saturation.

Antibodies to factor X. An antiserum to purified human factor X was prepared in a goat and its IgG fraction isolated as described earlier.¹¹ The IgG fraction gave a single precipitation line of identity on a double-immunodiffusion plate with purified factor X and normal plasma. A 100-fold dilution of the IgG fraction neutralized 60% of the factor X clotting activity in normal plasma. Adding the antibody to a reaction mixture of factor Xa, phospholipid, calcium ions, and factor VII prevented any measurable activation of the factor VII by factor Xa.

Preparation of anti-factor VII and anti-factor X columns. The immunoglobulin fraction of anti-factor VII and the purified IgG fraction of anti-factor X were coupled to CNBr-activated Sepharose 4B according to the manufacturer's technical bulletin at approximately 6 and 8 mg/mL packed beads, respectively. Deficient plasmas were passed through respective columns, and the plasma was eluted with TBS. Only those fractions of maximum refractive index were pooled to minimize the dilution of plasma (the plasma was diluted by 10% to 20% in this process).

Sources of the extrinsic pathway inhibitor (EPI). Whole plasma, barium-adsorbed plasma, and a partially purified reagent were used as sources of EPI. The partially purified reagent was prepared from a lipoprotein fraction obtained by ultracentrifugation of plasma to which sodium bromide was added to a final density of 1.21.¹² An apoprotein fraction was obtained by adding 8 vol of cold acetone to 1 vol of lipoprotein fraction and incubating overnight at -20 °C. The precipitate was separated by centrifugation, washed with diethyl ether, pelleted again, dried under nitrogen gas, and then resuspended at one tenth the initial volume in Tris-buffered saline containing 6 mol/L urea at pH 8.0. This suspension was loaded on Sephacryl S-200, which had been equilibrated with the same buffer, and was then eluted with the same buffer. Several protein peaks were obtained; a major protein peak made up primarily of apo-lipoprotein A-I contained most of the EPI. It was concentrated using an Amicon PM-30 membrane (Amicon Corp, Danvers, MA), dialyzed against TBS, and stored at -80 °C.

Preparation of ^3H -factor IX. Siayl ^3H -factor IX was prepared by the general technique of Van Lenten and Ashwell.¹³ The specific activity of different preparations varied between 2 to 4 $\times 10^8$ cpm/mg of protein. Labeled preparations retained 80% to 90% of the biologic activity of nonlabeled preparations as measured in a one-stage factor IX clotting assay.⁷

Measurement of factor IX activation. The rate of factor IX activation was monitored by measuring the ^3H -activation peptide release from the ^3H -factor IX by a modification¹⁴ of the technique described by Zur and Nemerson.¹⁵ Full activation of factor IX, as measured by SDS-polyacrylamide gel electrophoresis, yielded approximately 35% to 40% trichloroacetic acid-soluble counts.

Active site-inhibited factor Xa. An active site histidine-directed serine protease inhibitor, dansyl-glutamyl-glycyl-arginyl-chloro-

methyl ketone (DEGR-CK) was used to inhibit irreversibly the factor Xa activity. One hundred microliters of factor Xa (8.3 $\mu\text{mol/L}$) was incubated with 2 μL of DEGR-CK (7 mmol/L) for 15 minutes at 37 °C, and the excess inhibitor was then removed by dialysis against TBS. This treatment completely inhibited the factor Xa activity as measured in a factor Xa clotting assay.

RESULTS

Evidence that EPI acts against the factor VIIa-tissue factor complex. We knew from the earlier study⁴ that EPI inhibits either tissue factor itself or the factor VIIa/tissue factor complex. Therefore, we carried out an experiment in which the activation of factor IX was measured in factor VII-deficient plasma containing concentrations of tissue factor and of factor VIIa that left only a minimal excess of tissue factor and no significant free factor VII. These concentrations were determined from a preliminary experiment in a system containing ^3H -factor IX, calcium, 0.05 $\mu\text{g/mL}$ factor VIIa, no source of EPI, and increasing concentrations of tissue factor. At this factor VII concentration, increasing the tissue factor concentration above 20% did not increase the rate of activation of factor IX.

Therefore, an experimental reaction mixture was made to contain factor VII-deficient plasma (which had been passed through an anti-factor VII column), 20% (vol/vol) tissue factor, 0.05 $\mu\text{g/mL}$ factor VII, 5 $\mu\text{g/mL}$ ^3H -factor IX, and 5 mmol/L calcium. As shown in Fig 1, a plateau of activation was reached after only 4% of the trichloroacetic acid (TCA) soluble counts were released. The reaction mixture was then divided into aliquots to which first EDTA and then one of the following were added: tissue factor alone (20% vol/vol), factor VII alone (0.20 $\mu\text{g/mL}$), or tissue factor (20% vol/vol) plus factor VII (0.20 $\mu\text{g/mL}$). Following this, each reaction mixture was recalcified. As shown in Fig 1, adding tissue factor alone or adding factor VII alone failed to induce a further significant release of TCA-soluble counts. However, adding both reactants together resulted in a second wave of factor IX activation.

Fig 1. The effect of supplemental tissue factor, factor VIIa, or factor VIIa/tissue factor upon the progress of activation of ^3H -factor IX in factor VII-deficient plasma. The initial incubation mixture (O) contained ^3H -factor IX, 5.0 $\mu\text{g/mL}$; factor VIIa, 0.05 $\mu\text{g/mL}$; tissue factor, 20% (vol/vol); calcium, 10 mmol/L; and factor VII-deficient plasma, 75% (vol/vol). At one hour (arrow) an aliquot was left undisturbed (O), and EDTA, 12 mmol/L, was added to the remaining aliquots. Then the EDTA-treated aliquots were supplemented with one of the following: buffer, (●); factor VIIa, 0.20 $\mu\text{g/mL}$ (Δ); tissue factor, 20% (vol/vol) (Δ); and factor VIIa, 0.20 $\mu\text{g/mL}$, plus tissue factor, 20% (vol/vol) (□). Following this, the reactions were started again in EDTA-treated aliquots with calcium, 22 mmol/L.

In a supplemental experiment, ^{125}I -factor VII/particulate tissue factor/ Ca^{2+} was centrifuged, and the pellet was washed several times in buffer containing calcium to ensure that the persisting radioactivity of the pellet represented only ^{125}I -factor VII complexed with tissue factor. When the pellet was suspended in either buffer or factor VII-deficient plasma containing EDTA and centrifuged again, the majority of the counts were now found not in the pellet but in the supernatant. However, when the pellet was suspended in buffer or factor VII-deficient plasma containing EDTA but excess calcium was added before centrifugation, the majority of radioactivity was found in the pellet. This experiment provides evidence that adding EDTA under our experimental conditions dissociated a factor VIIa/tissue factor/ Ca^{2+} complex and that the dissociated complex could be reassociated by adding calcium again.

Therefore, one may conclude that in the data shown in Fig 1 an inhibited factor VIIa/tissue factor complex was first dissociated and then reassociated. The observation that under these conditions both tissue factor and factor VIIa were required to overcome inhibition by EPI provides strong evidence that EPI inhibits the enzymatic activity of the factor VIIa/tissue factor complex rather than the activity of only its tissue factor component.

Blunting of a second wave of activation of factor IX by supplementing reaction mixtures with additional EPI, factor X, or both. In a reaction mixture made with normal plasma and 20% (vol/vol) tissue factor, a plateau of ^3H -factor IX activation was reached after release of about 5% TCA-soluble counts. Since this reaction mixture contained normal plasma and therefore a tenfold higher factor VII concentration than that used in the reaction mixture of Fig 1, increasing the tissue factor concentration to 40% (vol/vol) allowed free factor VIIa in the mixture to form additional factor VIIa/tissue factor complex. The additional factor VIIa/tissue factor complex initiated a second wave of factor IX activation that was of greater amplitude than the first wave (see the uppermost curve of Fig 2). This suggested that inhibition of the initial factor VIIa/tissue factor complex had consumed inhibitory material in the reaction mixture. When supplemental EPI and factor X were added along with the second aliquot of tissue factor, then the second wave of factor

IX activation induced by additional tissue factor was markedly reduced (see the middle curve of Fig 2).

Adding either EPI or factor Xa alone also diminished the second wave of activation but to a lesser degree. Thus, in three experiments the mean values for TCA-soluble counts at the plateau of a second wave of activation were as follows: when only tissue factor was added, 24%; when tissue factor plus factor X, 8 $\mu\text{g}/\text{mL}$, were added, 18.6%; when tissue factor plus partially purified EPI were added, 17%; and when tissue factor plus both factor X and partially purified EPI were added, 11%.

Failure of active site-inhibited factor Xa to support EPI-induced inhibition. Either factor Xa treated with DEGR-CK to block its active site or untreated factor Xa was added to factor X-deficient plasma that had been passed through an anti-factor X column to remove traces of factor X. ^3H -factor IX, tissue factor, and calcium were added to complete the reaction mixture. The final concentrations were as follows: for factor Xa, 2.5 $\mu\text{g}/\text{mL}$; for tissue factor, 20% (vol/vol). The results were as follows: TCA-soluble counts released after two hours in factor X-deficient plasma with no added factor Xa, 22%; with added DEGR-CK-treated factor Xa, 19%; with added untreated factor Xa, 3.5%.

Failure of preliminary incubation of incomplete reaction mixtures with factor Xa to support the inhibition of the factor VIIa/tissue factor complex. Since the effect of factor Xa appeared to require its active site, we designed an experiment to test the hypothesis that factor Xa's role was enzymatically to convert factor VIIa/tissue factor/ Ca^{2+} into a complex susceptible to EPI. Factor Xa, 2.5 $\mu\text{g}/\text{mL}$, tissue factor, 20% (vol/vol), factor VII, 0.5 $\mu\text{g}/\text{mL}$, and calcium were incubated together for one hour at 37 $^{\circ}\text{C}$, after which anti-factor X antibodies were added to neutralize the factor Xa. After 20 minutes, a source of EPI (factor X-deficient plasma) and ^3H -factor IX were added, and the activation of factor IX was monitored. The activation of factor IX was not inhibited; the extent of activation (release of 30% TCA-soluble counts in two hours) did not differ from that of a negative control in which no factor Xa was added to the reaction mixture. In a positive control in which buffer instead of antibodies to factor Xa was added before the addition of the factor X-deficient plasma, the factor VIIa/tissue factor activity was fully inhibited (release of 4% TCA-soluble counts in two hours).

Additional experiments were carried out to test the hypothesis that factor Xa enzymatically converted EPI from an inert precursor to an active inhibitor. In one experiment (data not shown) factor X-deficient plasma as a source of EPI and factor VII was incubated for 60 minutes with factor Xa and calcium. Antibodies to factor X were then added and, 20 minutes later, tissue factor (20% vol/vol) and ^3H -factor IX. The activation of factor IX was not inhibited.

In a further experiment, barium-absorbed plasma (source of EPI), tissue factor (which also served as a source of phospholipid, a known cofactor for other reactions involving factor Xa), factor Xa, and calcium were incubated for 60 minutes before antibodies to factor X were added. Twenty minutes later, factor VIIa and ^3H -factor IX were added and the activation of factor IX monitored. As can be seen in Fig

Fig 2. Blunting by partially purified EPI and factor Xa of a second wave of factor IX activation induced in normal plasma by a second addition of tissue factor. The initial reaction mixture (O) contained normal plasma, 75% (vol/vol); tissue factor, 20% (vol/vol); and ^3H -factor IX, 5 $\mu\text{g}/\text{mL}$, and calcium, 10 mmol/L . After 60 minutes (arrow), further reactants were added to the aliquots as follows: buffer (●); tissue factor, 20% (vol/vol) (Δ); or tissue factor, 20% (vol/vol), factor X, 8 $\mu\text{g}/\text{mL}$, and EPI (▲).

3, factor IX was activated at the same rate as in a control mixture made without factor Xa. Thus, no evidence was obtained for a preliminary reaction between EPI and factor Xa, in the presence of phospholipid and calcium as potential cofactors, that bypassed the later need for factor Xa. One should also note in Fig 3 that if all components of the reaction mixture except the substrate were allowed to incubate with factor Xa, then its subsequent neutralization before the addition of the substrate did not impede the inhibition of factor VIIa/tissue factor enzymatic activity.

Binding of EPI to factor VIIa/tissue factor/ Ca^{2+} complex. A factor VII/particulate tissue factor/ Ca^{2+} complex was prepared for use in binding experiments with EPI by adding factor VII to particulate tissue factor in the presence of calcium, separating the pellet by centrifugation, and washing the resuspended pellet several times with calcium-containing buffer. The final resuspended factor VII/tissue factor/ Ca^{2+} complex clotted both recalcified normal plasma and recalcified factor VII deficient plasma in 23 seconds.

This factor VII/tissue factor/ Ca^{2+} complex (25% vol/vol) was incubated with barium-absorbed plasma or buffer (barium-absorbed plasma control), calcium, cold factor IX (5 $\mu\text{g}/\text{mL}$), and either factor Xa or buffer (factor Xa control). (The cold factor IX was included to allow generation of factor VIIa independent of the presence or absence of factor Xa in reaction mixtures.) After incubation for two hours at 37 °C, the factor VIIa/tissue factor complex was isolated by centrifugation and the resultant pellet washed several times in calcium-containing buffer. As shown in Fig 4, when both

Fig 3. Evidence that tissue factor, factor VIIa, barium-absorbed plasma (source of EPI), Ca^{2+} , must all be present for factor Xa to support inhibition. Barium-absorbed plasma and tissue factor were incubated for one hour at 37 °C with the following additional reactants: (▲) factor Xa, Ca^{2+} ; (●) factor Xa, factor VIIa; (△) factor VIIa, Ca^{2+} ; and, (○) factor Xa, factor VIIa, Ca^{2+} . Then, factor Xa was neutralized with antibodies to factor X (10% vol/vol) for 20 minutes at room temperature. Following this, factor VIIa or Ca^{2+} were added to reaction mixtures that lacked these reactants during the first incubation period. ^3H -factor IX was added to all mixtures at a final concentration of 5.0 $\mu\text{g}/\text{mL}$. The final concentrations of other reactants were as follows: barium-absorbed plasma, 66% (vol/vol); factor VIIa, 0.5 $\mu\text{g}/\text{mL}$; tissue factor, 20% (vol/vol); factor Xa, 2.5 $\mu\text{g}/\text{mL}$; and Ca^{2+} , 10 mmol/L.

barium-absorbed plasma (source of EPI) and factor Xa had been present in the incubation mixture, the resuspended pellet had a markedly diminished ability to activate ^3H -factor IX. In contrast, when control buffer had replaced either barium-absorbed plasma or factor Xa in the incubation mixture, the resuspended factor VIIa/tissue factor complex retained full enzymatic activity. These differences were also demonstrable in a clotting assay; a resuspended, inhibited pellet clotted recalcified factor VII-deficient plasma in 50 seconds whereas resuspended uninhibited pellets clotted the plasma in 26 seconds.

These experiments provided strong indirect evidence that inhibitory activity bound to the factor VIIa/tissue factor complex in the presence of EPI, factor Xa, and calcium. They were incomplete, however, in that they did not test whether EPI could bind to a pellet separated from an incubation mixture lacking factor VII. Therefore, in a further experiment, 0.4 mL of particulate tissue factor preparation was incubated with partially purified EPI or buffer (control) and the following additional reactants: (1) factor VII (0.2 $\mu\text{g}/\text{mL}$), factor Xa (2.5 $\mu\text{g}/\text{mL}$), and calcium; and (2) buffer, factor Xa (2.5 $\mu\text{g}/\text{mL}$), and calcium. After a two-hour incubation, the pellets were isolated, washed, and tested for enzymatic activity in a mixture containing factor VII (0.2 $\mu\text{g}/\text{mL}$), factor Xa (2.5 $\mu\text{g}/\text{mL}$), and ^3H -factor IX. As apparent from the resultant curves of factor IX activation (Fig 5), inhibition of the pellet required not only the presence of factor Xa but also the formation of the factor VIIa/tissue factor/ Ca^{2+} complex. These experiments also suggest the possible binding of inhibitor to the factor VIIa/tissue factor/ Ca^{2+} complex in the presence of factor Xa.

If inhibitory material binds to a pellet, one should be able to demonstrate the loss of inhibitory activity in the supernatant. As the experiments summarized in Fig 6 show, when incubation mixtures made with particulate tissue factor, factor VII, factor Xa, partially purified EPI, and calcium were centrifuged, the resultant supernatant was unable to serve as a source of EPI for a second incubation mixture. In contrast, control supernatants from incubation mixtures lacking factor VIIa or factor Xa retained their ability to

Fig 4. Activation of ^3H -factor IX by resuspended factor VIIa/tissue factor pellets from different types of initial reaction mixtures. Different types of pellets resuspended in calcium-containing buffer were incubated with ^3H -factor IX, 5 $\mu\text{g}/\text{mL}$, and Ca^{2+} , 10 mmol/L, and the activation of factor IX monitored. The pellets were obtained by centrifugation of incubation mixtures containing particulate tissue factor, factor VII, factor IX, Ca^{2+} , and added reactants as follow: buffer (○), barium-absorbed plasma (●), and barium-absorbed plasma and factor Xa (▲). See the text for further details.

Fig 5. Evidence that a pellet prepared from an incubation mixture containing tissue factor, EPI, factor Xa, and Ca^{2+} , but not containing factor VII, possessed tissue factor activity and did not possess EPI activity. Reaction mixtures contained particulate tissue factor and other reactants as follows: (●) EPI, factor VII, factor Xa, Ca^{2+} ; (○) EPI, factor Xa, Ca^{2+} ; and (Δ) buffer, factor VII, factor Xa, Ca^{2+} . After two hours' incubation at 37 °C, pellets were obtained by centrifugation of incubation mixtures, washed and resuspended in calcium-containing buffer, and tested in the following system: resuspended pellet; factor VII (0.05 $\mu\text{g}/\text{mL}$), factor Xa (2.5 $\mu\text{g}/\text{mL}$), ^3H -factor IX (5.0 $\mu\text{g}/\text{mL}$), and calcium (10 mmol/L).

serve as a source of EPI for a second incubation mixture. These data not only confirm the binding of EPI to the factor VIIa/tissue factor complex but provide further evidence that EPI does not bind to tissue factor alone.

Recovery of tissue factor activity from the inhibited factor VIIa/tissue factor complex. Factor VIIa/tissue factor pellets prepared under conditions that would either inhibit enzymatic activity or would not (Fig 4) and were resuspended in buffer containing 5 mmol/l EDTA, and the particulate tissue factor was pelleted by centrifugation. After being washed several times with EDTA-containing buffer, the pellets were resuspended in calcium-containing buffer. Then, purified factor VII, 0.25 $\mu\text{g}/\text{mL}$, and ^3H -factor IX, 5.0 $\mu\text{g}/\text{mL}$, were added and the activation of factor IX monitored. As can be seen in Fig 7, the tissue factor recovered from an inhibited complex could support the activation of factor IX about as effectively as could tissue factor recovered from uninhibited complexes.

Experiments with purified tissue factor. After a technique was developed to purify tissue factor, selected additional experiments were carried out to confirm results obtained with crude tissue factor preparations. As with the

Fig 6. Absence of EPI activity in a supernatant of a reaction mixture made with particulate tissue factor, partially purified EPI, factor VII, factor Xa, and Ca^{2+} . Reaction mixtures contained particulate tissue factor and other reactants as follows: (Δ) EPI, factor VII, factor Xa, Ca^{2+} ; (●) EPI, Ca^{2+} ; and (Δ) buffer, factor VII, factor Xa, Ca^{2+} . After a one-hour incubation at 37 °C, the reaction mixtures were centrifuged, and the supernatants were tested for their EPI activity. The test system was as follows: supernatant; tissue factor, 10% (vol/vol); factor VIIa, 0.05 $\mu\text{g}/\text{mL}$; factor Xa, 2.5 $\mu\text{g}/\text{mL}$; ^3H -factor IX, 5 $\mu\text{g}/\text{mL}$; and Ca^{2+} , 10 mmol/L.

Fig 7. Evidence that tissue factor retains its activity after dissociation from an inhibited factor VIIa/tissue factor complex. After two hours' incubation at 37 °C, the factor VIIa/tissue factor/ Ca^{2+} complex was pelleted from incubation mixtures made with factor VII, particulate tissue factor, factor IX (to activate factor VII in mixtures that did not contain factor Xa), calcium and the following: (○) factor Xa, buffer; (Δ) barium-absorbed plasma, buffer; and (□) factor Xa, barium-absorbed plasma-containing buffer. Then, pellets were resuspended in EDTA-containing buffer to dissociate the tissue factor. The dissociated tissue factor was washed twice in EDTA-containing buffer and resuspended in calcium-containing buffer. The tissue factor was then tested for activity as measured by its ability to support the activation of ^3H -factor IX in a reaction mixture containing factor VII, calcium, and ^3H -factor IX.

crude preparations, both EPI and factor Xa were required to inhibit the enzymatic activity of a factor VIIa/purified tissue factor complex. Furthermore, as with the crude preparation, DEGR-CK-treated factor Xa failed to support EPI-induced inhibition.

DISCUSSION

In earlier work from this laboratory, a plasma mechanism for inhibiting the enzymatic activity of factor VIIa/tissue factor was described that involves both a plasma-inhibitory material and factor Xa.⁴ The earlier data did not allow us to conclude whether inhibition stemmed from neutralization of only the tissue factor component of the complex or from neutralization of the complex as a whole.

The data presented herein now establish that inhibition induced by the plasma-inhibitory material (provisionally called EPI) and factor Xa results from the inhibition of the complex as a whole. Thus, when an inhibited factor VIIa/tissue factor complex was dissociated with EDTA and then reassociated with calcium under conditions in which the reaction mixture contained an excess of free factor VIIa or of free tissue factor but not of both, a new factor VIIa/tissue factor complex with enzymatic activity was not demonstrable. Only when the reaction mixture contained both additional factor VII and tissue factor did recalcified reaction mixtures exhibit new factor VIIa/tissue factor enzymatic activity (Fig 1).

If the reaction mixtures initially contained excess free factor VII, then adding more tissue factor alone induced a second wave of factor VIIa/tissue factor enzymatic activity. Such a second wave often activated more factor IX than did the first wave of activity (Fig 2). However, one could curtail the second wave of enzymatic activity by supplementing the reaction mixture with additional EPI and factor X (Fig 2). It would appear, therefore, that normal plasma contains a

concentration of EPI sufficient to limit extrinsic coagulation initiated by a low concentration of the factor VII/tissue factor complex but insufficient to limit extrinsic coagulation initiated by a higher concentration of the factor VII/tissue factor complex (such as might occur pathologically when the contact of blood with brain tissue after head trauma leads to extensive defibrination¹⁶).

Inhibition of the factor VIIa/tissue factor enzymatic activity does not inhibit tissue factor irreversibly. Tissue factor resuspended from a pellet recovered after dissociating an inhibited factor VIIa/tissue factor complex retained its ability to function as a cofactor in a new factor VIIa/tissue factor complex (Fig 7). Moreover, the supernatant obtained after centrifuging a dissociated, inhibited factor VIIa/tissue factor complex had factor VII(a) coagulant activity. For example, in one experiment the supernatant gave a clotting time in a one-stage factor VII assay of 26 seconds as compared with the inhibited reaction mixture before decalcification, which gave a clotting time of 53 seconds in the assay. However, present data are inadequate to estimate the extent of recovery of factor VII activity in supernatants of decalcified, inhibited complexes. This will require the use of the coupled amidolytic factor VII assay technique¹⁷ to eliminate the differences in measured factor VII activity stemming from a variation in the ratios of factor VIIa to factor VII in supernatants of experimental and control reaction mixtures.

In experiments carried out before the discovery of factor X, Hjort¹⁸ found that the increased coagulant activity resulting from the incubation of "proconvertin reagent," tissue factor, and calcium (which was referred to as convertin) could be inhibited by a material in barium-absorbed serum (which was referred to as anticonvertin). It is now clear that Hjort's "proconvertin reagent" contained both factor VII and factor X and, therefore, that factor Xa was generated in his reaction mixtures. Thus, what we have called EPI almost surely is Hjort's original anticonvertin activity. This possibility receives further support from Hjort's observation¹⁸ that both tissue factor and proconvertin (factor VII) activity could be recovered after decalcification of inhibited "convertin."

Recent observations of inhibition of the factor VIIa/tissue factor enzymatic activity by other investigators also appear related to the EPI-factor Xa mechanism. In 1981, Carson¹⁹ reported that plasma high-density lipoproteins could inhibit the factor VIIa/tissue factor activation of factor X. Since we can recover about 50% of the total EPI activity of plasma in a lipoprotein fraction of plasma, the activity Carson described very probably is EPI. His use of factor X as the substrate for factor VIIa/tissue factor masked the need for factor Xa to observe the inhibitory effect. The experiments on the inhibition of activated factor VII by normal plasma reported by Dahl and coworkers²⁰ are also best explained by an EPI-factor Xa-induced inhibition of the factor VIIa/tissue factor complex. Morrison and Jesty's²¹ report that factor Xa inhibits the tissue factor-dependent activation of factor IX in human plasma can be accounted for by the requirement for factor Xa for the inhibitory effect of EPI. More recently, Hubbard and Jennings²² have also provided data showing the

participation of factor Xa in the inhibition of tissue factor activity by a plasma component (presumably EPI).

The mechanism of factor Xa's participation in the inhibitory reaction is not yet known. Since inhibiting factor Xa's active site abolishes EPI's ability to participate in the inhibitory reaction, it would be logical to assume that factor Xa acts enzymatically. Yet, in experiments in which factor Xa was first incubated with components of incomplete reaction mixtures and then neutralized with anti-factor X antibodies, we could not obtain evidence that factor Xa's role was to act enzymatically upon EPI in the absence of factor VIIa/tissue factor or, conversely, upon factor VIIa/tissue factor in the absence of EPI.

If all components except the factor IX substrate were allowed to incubate together and the factor Xa was neutralized with antibodies before adding the substrate, then factor VIIa/tissue factor enzymatic activity was inhibited (Fig 3). Thus, factor Xa appears to exert its role in a reaction independent of the substrate. The data as a whole are compatible with a hypothesis that factor Xa acts enzymatically upon EPI but only when factor VIIa, tissue factor, and calcium are also present. This hypothesis will be tested further when a more highly purified EPI preparation becomes available.

How EPI induces inhibition is also not yet understood. As already mentioned and, indeed, as Hjort probably first showed in 1957,¹⁸ EPI does not irreversibly inactivate tissue factor. Nor does EPI appear to inactivate factor VII(a). Thus, it is most unlikely that EPI acts enzymatically. The evidence suggesting that EPI is consumed in the inhibitory reaction further supports this conclusion. EPI appears to bind to the factor VIIa/tissue factor complex, for its activity is not demonstrable in the supernatant after centrifugation of an inhibited factor VIIa/tissue factor complex (Fig 6). However, EPI does remain in the supernatant of a pelleted factor VIIa/tissue factor complex formed in a reaction mixture lacking factor Xa. We take these results to mean that binding of EPI to a factor VIIa/tissue factor complex is required for EPI's inhibitory effect. This, plus an apparently limited concentration of EPI in plasma and the evidence that adding a low concentration of tissue factor to plasma leaves a large excess of free factor VII in the plasma,²³ would explain why adding a high concentration of tissue factor to plasma can bypass the inhibitory effect of EPI upon factor VIIa/tissue factor activity.

The bleeding of patients with hemophilia establishes that the extrinsic pathway, acting alone, cannot generate sufficient factor Xa for normal hemostasis. Inhibition of factor VIIa/tissue factor activity triggered by the factor Xa it generates could account for the need for a factor IXa/factor VIIIa/phospholipid activator for continuing generation of factor Xa during hemostasis. If so, the EPI-factor Xa mechanism for the inhibition of factor VIIa/tissue factor enzymatic activity could represent a key regulatory reaction for normal hemostasis.

ACKNOWLEDGMENT

We wish to acknowledge the contribution made by A. Zivelin in the partial purification of EPI.

Cellular and Subcellular Localization of the Bactericidal/Permeability-Increasing Protein of Neutrophils

By Jerrold Weiss and Inge Olsson

Human and rabbit polymorphonuclear leukocytes contain a bactericidal/permeability-increasing protein (BPI), a potent cytotoxin active specifically against gram-negative bacteria. To identify the cell population(s) producing BPI, we have examined mature and immature human blood cells for BPI by immunofluorescence of intact cells and radioimmunoassay and bioassay of cell extracts. By immunofluorescence and radioimmunoassay of cells from peripheral blood, BPI was detected only in neutrophils; immunofluorescent staining was punctate, indicative of the granule localization of BPI. Nearly all (>90%) BPI was recovered during the subcellular fractionation of neutrophils (N_2 cavitation and discontinuous Percoll gradient) in fractions containing primary granules. Little BPI was released from intact cells during degranulation (cytochalasin B and f-Met-Leu-Phe) or could be extracted from isolated granules with salt or weak acid, which suggests that most granule-associated BPI is membrane bound. Double staining of bone

marrow smears for BPI and lactoferrin revealed BPI only in neutrophil precursors including (pro)myelocytelike cells lacking lactoferrin, a marker of neutrophil secondary granules. Of several human cell lines tested, only the promyelocytelike HL-60 (and to a lesser extent, KG-1) cells contained BPI. BPI was present in a more mature subpopulation (<25%) of untreated HL-60 cells, recognized by surface marker analysis (rosetting with IgG-sensitized sheep RBC, the absence of proliferation-associated cell surface antigen). Induction of neutrophilic or monocytic differentiation caused, respectively, a small (approximately 50%) rise or fall in the BPI content. These findings indicate that BPI is a specific product of the neutrophil lineage and, hence, of the specialized cytotoxic apparatus of the neutrophil that plays an essential role in host defense *v* gram-negative bacteria.

© 1987 by Grune & Stratton, Inc.

NEUTROPHILIC (heterophilic) polymorphonuclear leukocytes (PMN) are highly specialized phagocytic cells that play a primary role in defense of the host against invading microorganisms.¹ For this purpose, PMN elaborate a variety of microbicidal agents.¹⁻⁵ One of these cytotoxic substances is a membrane-active cationic protein with potent cytotoxic activity directed specifically against several species of gram-negative bacteria.³ We have isolated this protein from human neutrophils and a very similar protein from rabbit PMN.^{6,7} In both species, this bactericidal/permeability-increasing protein (BPI) appears to play an important role in the killing of several species of gram-negative bacteria by PMN.^{3,8,9}

Both human and rabbit BPI are localized in cytoplasmic granules,^{6,10,11} specialized organelles that contribute greatly to the antimicrobial function of PMN.^{1-5,12} Preliminary examination of other phagocytic and nonphagocytic blood cells (bioassay of cell extracts) has suggested that BPI is present predominantly, if not solely, in neutrophilic (heterophilic) PMN.^{6,10} We have now used immunofluorescence and radioimmune assays to demonstrate that BPI is a specific

product of the neutrophil that is synthesized at or around the promyelocyte stage of differentiation and stored in the primary granules. Studies on the promyelocytelike leukemic cell line HL-60 suggest that the synthesis of BPI may occur after that of the primary granule protein myeloperoxidase.

MATERIALS AND METHODS

Cells. Heparinized venous blood from healthy volunteers and bone marrow aspirates collected for diagnostic purposes by the hematology service were obtained after informed consent. Only bone marrow samples with the normal myeloid spectrum were used. Mononuclear and polymorphonuclear leukocytes and erythrocytes were separated by sedimentation on discontinuous density gradients of Ficoll 400/sodium diatrizoate (Sigma Chemical Co, St Louis).¹³ Platelet-rich suspensions were collected from outdated (one to five days) blood obtained from the New York Blood Bank as previously described.¹⁴

All cell lines were maintained in culture at 2×10^4 to 2×10^6 cells/mL in RPMI 1640 medium supplemented with 10% to 20% heat-inactivated fetal bovine serum, 2 mmol/L glutamine, 100 U/mL penicillin, and 100 μ g/mL streptomycin.

All cells were washed twice with Dulbecco's phosphate-buffered saline supplemented with 0.2% (wt/vol) bovine serum albumin (PBSA) before use. Cell smears were prepared by cytospin (5×10^4 cells in 0.1 mL PBSA; Shandon Southern Instruments, Inc, Sewickley, PA) and stained (May-Grünwald-Giemsa) for differential counting. Eosinophils and basophils were also identified by their characteristic granular appearance seen by phase-contrast microscopy.

Differentiated HL-60 cells were recognized by the reduction of nitroblue tetrazolium after stimulation with phorbol myristate acetate (1 μ g/mL)¹⁵ and by the expression of nonspecific esterase activity.¹⁶

Fractionation of HL-60 cells by rosetting with IgG-coated sheep erythrocytes. HL-60 cells were incubated with an equal number of sheep erythrocytes that had been pretreated with a subagglutinating dose of rabbit (antisheep erythrocyte) antiserum. After the incubation (ten minutes at 4 °C followed by centrifugation at 50 to 100 g for five minutes and an additional 60-minute incubation at 4 °C), rosetting and nonrosetting cells were separated by sedimentation in a density gradient of Isopaque-Ficoll. After separation, erythrocytes were lysed by brief treatment with distilled water.

Antibodies and immunoblotting. Antisera to human BPI and myeloperoxidase were obtained after immunization of New Zealand White rabbits with purified BPI⁶ and myeloperoxidase,¹⁷ respectively. Preimmune sera were collected from the same rabbits before immunization. The mouse monoclonal antibody Y201¹⁸ was generously provided by Dr Mary B. Todd (Department of Medicine, Yale University School of Medicine, New Haven, CT).

The specificity of the rabbit (anti-BPI) serum was confirmed by Western blot analysis of the serum against a crude extract of neutrophils (Fig 1). Neutrophils (10^8 /mL) were extracted with 1% Triton X-100/1% sodium deoxycholate/1 mmol/L phenylmethane-sulfonyl fluoride by sonication for 10 seconds at 40 W (4°C) followed by a 60-minute incubation at 15 to 20°C. Solubilized proteins were collected by centrifugation at 20,000 g for 20 minutes, separated by electrophoresis in sodium dodecyl sulfate-polyacrylamide gels,¹⁹ and transferred to nitrocellulose by electroblotting.²⁰ The nitrocellulose paper containing transferred proteins was then treated sequentially with 3% BSA in 10 mmol/L Tris-buffered saline (TBS), pH 7.4; anti-BPI serum diluted 100-fold in 3% BSA-TBS containing 0.5% Nonidet P-40 (NP40)/5 mmol/L EDTA; and, after washing with TBS, [¹²⁵I]goat (antirabbit IgG) F(ab')₂ (New England Nuclear, Boston; 100,000 cpm/mL) in 3% BSA-TBS and 0.5% NP40/5 mmol/L EDTA. After washing in TBS, the paper was dried and exposed using Kodak X-Omat AR film.

Immunofluorescence. For detection of intracellular (granule) proteins, cell smears (cytospin) were fixed for one minute at 4°C in buffered formalin acetone.²¹ The fixed smears were washed in PBS, rinsed with PBSA, and overlaid for ten minutes at room temperature with 10% heat-treated pooled human serum to occupy the nonspecific binding sites. After rinsing with PBSA, the smears were overlaid for 30 minutes with rabbit (anti-BPI) or (antimyeloperoxidase) serum diluted 100- to 300-fold in PBSA. After washing, the smears were overlaid for 30 minutes with rhodamine-labeled swine (antirabbit Ig) Ig (Accurate Chemical & Scientific Corp, Westbury, NY) diluted 80-fold with PBSA. Excess rhodamine-labeled Ig was removed in three washes (30 minutes) with PBS. For double staining of BPI and lactoferrin, the smears were then soaked in 1% rabbit

serum (to occupy the remaining binding sites on swine [antirabbit Ig] Ig), rinsed in PBSA, overlaid for 30 minutes with 1% rabbit (antihuman lactoferrin) F(ab')₂ conjugated with fluorescein isothiocyanate (FITC), and washed with PBS.

For double staining of BPI and the cell surface antigen recognized by the mouse monoclonal antibody Y201, unfixed cells were treated in suspension at 4°C with the murine monoclonal¹⁸ and, after washing, with FITC-labeled goat (antimouse IgG plus IgM) Ig (Accurate Chemical & Scientific Corp). After washing, cell smears were prepared by cytopsin and then fixed and stained for BPI as was described.

After staining, the smears were covered with glycerol:PBS (9:1, vol/vol) containing 1 mg/mL *p*-phenylenediamine²² and a coverslip and examined under oil using a Leitz Orthoplan fluorescent microscope (E. Leitz, Inc, Rockleigh, NJ) with excitation and barrier filters for FITC and rhodamine staining. Photographs were taken with Kodak Tri-X pan (ASA 400) film at approximately 1,000× magnification.

Degranulation. Neutrophils (4.5×10^7 /mL) were incubated at 37°C in 20 mmol/L Hepes-buffered saline containing 45% (vol/vol) Hanks' buffered solution (M.A. Bioproducts, Walkersville, MD), pH 7.4, for five minutes in the presence and absence of 5 µg/mL cytochalasin B (Aldrich Chemical Co, Milwaukee) and then for 20 minutes with or without f-Met-Leu-Phe (Sigma Chemical Co). Cells and extracellular medium were separated by centrifugation (250 g, 10 minutes). Cells were extracted either with 0.2% Triton X-100 or as described for immunoblotting.

Subcellular fractionation. Primary and secondary granules of the neutrophils were separated as previously described²³ by N₂ cavitation of purified neutrophils and sedimentation of the postnuclear supernatant in a discontinuous Percoll (Pharmacia Fine Chemicals, Piscataway, NJ) gradient. The fractions were collected from the top of the gradients with a Densi-Flow pump (Buchler Instruments, Fort Lee, NJ). The particulate fractions were localized by measuring the absorbance at 450 nm, and fractions corresponding to separated α and β bands were pooled.

Extraction of granule proteins. A mixed granule-rich fraction of neutrophils was collected by sedimentation (10,000 g, 20 minutes) of the postnuclear supernatant obtained after N₂ cavitation. The granule-rich pellet was resuspended at 2×10^8 cell equivalents/mL in various media (see Table 2 below) by sonication (10 seconds at 40 to 50 W at 4°C) and then incubated at 4°C for one hour. Solubilized material was isolated by centrifugation at 23,000 g for 20 minutes. The pellet was resuspended as before, and the extraction was repeated. The remaining insoluble residue was extracted with 0.2% Triton X-100 or 1% Triton X-100/1% sodium deoxycholate before assay.

Radioimmunoassay. BPI, myeloperoxidase, and lactoferrin were measured in Triton X-100/sodium deoxycholate extracts of whole cells or subcellular fractions by dot blotting on nitrocellulose following essentially the same procedure as described for immunoblotting and elsewhere.⁹ Rabbit (antihuman lactoferrin) Ig was purchased from Accurate Chemicals & Scientific Corp. Standard curves with purified BPI, myeloperoxidase and lactoferrin (Calbiochem, La Jolla, CA) were used to quantitate the protein content in crude extracts. The amount of [¹²⁵I]-goat (antirabbit Ig) F(ab')₂ bound to strips treated with preimmune serum or in the absence of added antigen was <5% of the maximum binding to strips treated with immune serum and antigen and was subtracted for quantitation.

Bioassay of BPI. The BPI content of whole cell extracts was also determined by measuring the bactericidal activity of 0.16 N H₂SO₄ extracts toward BPI-sensitive *Escherichia coli* S15⁶ in comparison with that of purified BPI. The BPI content assessed by bioassay and radioimmunoassay matched closely. The bactericidal activity toward *E. coli* of crude extracts could be blocked by goat (anti-BPI)

Fig 1. Specificity of rabbit (anti-BPI) serum shown by immunoblotting. A crude extract of neutrophils was electrophoresed in duplicate in a sodium dodecyl sulfate-(10%) polyacrylamide gel. (A) The sample was stained with Coomassie blue. (B) The sample was analyzed by immunoblotting as described in Materials and Methods. Migration of BPI is indicated.

IgG,⁸ thereby confirming that the bioactivity was specifically attributable to BPI.

Miscellaneous. Protein was measured by the method of Lowry et al²⁴, using BSA as a standard. Elastase was measured by hydrolysis of methoxysuccinyl-(L-alanyl)₂-L-prolyl-L-valyl-*p*-nitroanilide.²⁵ Purified BPI was radioiodinated using iodogen-coated beads (Pro Tag; J.T. Baker Co, Philadelphia).²⁶

RESULTS

BPI is present exclusively in neutrophils. To identify blood cells that contain BPI, we treated fixed smears of mixed human peripheral blood cells with rabbit anti-BPI serum and, after washing, rhodamine-labeled swine (anti-rabbit Ig) antibodies. After this treatment, only neutrophils were brightly fluorescent (Fig 2A and B, Table 1). Lymphocytes, monocytes, erythrocytes, platelets, and basophils showed little or no fluorescence. Eosinophils exhibited pale fluorescence (Fig 2A), but as previously noted by others,²⁷ this was nonspecific (ie, of equal intensity after treatment of the cells with immune or preimmune serum). Moreover, unlike the rhodamine staining of neutrophils, staining of eosinophils was also visible with filters for fluorescein excitation and emission. Neutrophil staining was very similar from cell to cell and from individual to individual ($n > 50$) and typically had a punctate appearance consistent with the localization of BPI in cytoplasmic granules.^{6,11} No staining of neutrophils was seen when the cells were treated with either preimmune rabbit serum or immune serum depleted of anti-BPI antibodies by pretreatment with purified BPI.

The BPI content of human neutrophils was assessed more quantitatively by radioimmunoassay of purified neutrophil preparations (Table 1). Neutrophils contain $65 \pm 6.3 \mu\text{g}$ of BPI/ 10^8 cells (range, 41 to $88 \mu\text{g}/10^8$ cells; $n = 5$) representing $0.6\% \pm 0.1\%$ of the total neutrophil protein. In contrast, mononuclear leukocytes and platelet-rich suspensions contain virtually no BPI-like immunoreactive material (Table 1).

Localization of BPI in primary granules of neutrophils. To determine in which of the two main granule populations of the neutrophils BPI is localized, postnuclear supernatants of disrupted neutrophils were subjected to density gradient centrifugation in discontinuous Percoll gradients. As originally described,²³ this procedure yielded two granule-rich fractions (α , [$\rho = 1.13 \text{ g/mL}$] and β [$\rho = 1.08 \text{ g/mL}$]) in which the primary and secondary granules were nearly completely separated as judged by the distribution of myeloperoxidase and lactoferrin (Table 2).²³ BPI was recov-

ered almost exclusively in the α fraction (Table 2), which indicates that it is localized in the primary granules.

In comparison with myeloperoxidase, lactoferrin, and elastase (another primary granule protein), very little BPI is released into the extracellular medium during treatment of intact neutrophils with cytochalasin B and f-Met-Leu-Phe (Table 2). That BPI is more tightly associated with the granules than are these other granule proteins is also indicated by the finding that treatment of isolated granules with either salt (0.15 to 1.0 mol/L NaCl) or weak acid (0.2 mol/L sodium acetate/acetic acid [pH 4.0]) releases nearly all the myeloperoxidase, lactoferrin, and elastase in soluble form but only a small proportion of BPI (Table 2). Purified ¹²⁵I-BPI added to extracted granules is recovered in the soluble phase, thereby indicating that the granule-associated BPI is tightly membrane bound and not artifactually trapped in the insoluble granule residue. Treatment with 1% Triton X-100 and sodium deoxycholate solubilizes BPI as assessed by radioimmunoassay and Western blots (data not shown).

Immunofluorescent staining of BPI in bone marrow cells. Because the primary granules are formed before the secondary granules,²⁸ BPI may be expected to appear before lactoferrin during myeloid differentiation. Indeed, double immunofluorescent staining of BPI and lactoferrin in human bone marrow cells revealed BPI-positive/lactoferrin-negative precursor cells (Figs 3A and B) that morphologically resembled early myeloid precursors (eg, [pro]myelocytes) that contain only primary granules. All lactoferrin-positive cells also stained positively for BPI and resembled later myeloid precursors that contain both primary and secondary granules (Figs 3A and B).

Presence of BPI in promyelocytelike cell line(s). To substantiate further that BPI is a specific product of the

§Percentage of protein recovered from the supernatant at 20,000 g for 20 minutes after treatment of the mixed granule-rich fraction with salt (0.15 or 1.0 mol/L NaCl $\pm$ 20 mmol/L Hepes, pH 7.3; mean $\pm$ SEM; $n \geq 4$) or weak acid (0.2 mol/L sodium acetate/acetic acid, pH 4.0; range of two determinations).

neutrophil lineage and is present only in myeloid cells that contain primary granules, we examined several leukemic and nonleukemic human cell lines for BPI. Only cell lines with promyelocytelike cells (HL-60²⁹ and, to a lesser extent, KG-1²⁹) contained BPI as judged by immunofluorescence as well as by radioimmunoassay and bioassay of the cell extracts (Table 3). No BPI was detected in myeloid cell lines that do not mature beyond the myeloblast stage or in cells of other lineages.

Even in the HL-60 cell line (passage 30 to 40) with its predominance of promyelocytelike cells rich in myeloperoxidase^{29,34} (Table 4), only relatively few cells are BPI-positive, and the overall BPI content is low compared with mature neutrophils (either of normal or leukemic origin) (Table 3). Brightly staining BPI-positive cells are significantly enriched in the small subpopulation (about 15%)³⁵ of HL-60 cells that form rosettes with IgG-sensitized sheep erythrocytes (ie, Fc receptor-positive) and reciprocally diminished in the Fc receptor-negative cells (Table 4). More striking is the

almost mutually exclusive cellular localization of BPI and a cell surface antigen associated with cellular proliferative capacity that is recognized by monoclonal antibody Y201¹⁸ (Table 4, Fig 4A and B). As judged by double immunofluorescence, nearly all (88% $\pm$ 3%) BPI-positive cells are Y201-negative, which represents the less proliferative subpopulation (about 20% to 35%) of HL-60 cells.¹⁸ In contrast, Y201-positive and Y201-negative cells show nearly identical staining for myeloperoxidase (Table 4); only 26% $\pm$ 5% of the myeloperoxidase-positive HL-60 cells are Y201-negative.

Because the absence of the Y201 surface antigen and the presence of Fc receptors might reflect a more mature phenotype of the BPI-positive cells, we examined the effect of further differentiation in vitro on the BPI content of HL-60 cells. Treatment of HL-60 cells for four to six days with either retinoic acid (10^{-6} mol/L) or dimethyl sulfoxide (DMSO) (1.3%) induces differentiation in a granulocytic (neutrophilic) direction^{36,37} and increased the fraction of BPI-positive cells by up to twofold and the overall cellular content of BPI by 50% (Table 5). In contrast, during the same treatment, the myeloperoxidase content of HL-60 cells declines by two- to three-fold (Table 5).^{34,38} The increase in BPI content is restricted to granulocytic (neutrophilic) differentiation; treatment with either phorbol myristate acetate (10^{-8} mol/L) or a T cell-derived differentiation-inducing factor³⁹ induces monocyte/macrophage-like cellular characteristics^{39,40} and a reduction in the BPI content as judged by immunofluorescence (Table 5). Incubation of HL-60 cells in slightly alkaline medium induces eosinophilic differentiation⁴¹ and also a reduction in BPI-specific immunofluorescent staining (not shown).

DISCUSSION

As judged by immunofluorescence of intact cells and radioimmunoassay and bioassay of cell extracts, BPI occurs only in neutrophils and its precursors in peripheral blood or bone marrow and in myeloid (leukemic) cell lines. Along with other antimicrobial proteins and peptides of the neutrophil,^{4,5,42} BPI is located in the primary granules. BPI differs from other primary granule proteins in that it remains sedimentable under conditions that result in solubilization/release of proteins such as elastase and myeloperoxidase (Table 2). The highly basic BPI also exhibits hydrophobic properties. These are revealed in its interaction with target

bacteria⁴³ and also with the synthetic hydrophobic matrices including phenyl-Sepharose and reverse-phase columns (unpublished observations), thus distinguishing BPI from other highly cationic granule proteins. The combination of strong positive charge and lipophilic properties may account for the firm association of BPI with the granule membrane.

Treatment of isolated granules with salt and/or weak acid reproducibly extracts 25% to 40% of the granule-associated BPI (Table 2). Strong acid (0.16 N H₂SO₄) is needed to solubilize most of the BPI.⁶ Whether the differential solubilization of BPI reflects heterogeneity in the BPI molecules or in their association with granule constituents^{44,45} and hence in their bioavailability for antibacterial action has not yet been determined. The localization of BPI in primary granules and in association with their membranes may favor the retention of this bactericidal agent within phagolysosomes⁴² and, consequently, its intracellular action against ingested bacteria.^{8,9}

Recent studies of the biosynthesis of myeloperoxidase and lactoferrin during myeloid differentiation have suggested that these granule proteins are produced during the limited time frame when granules are formed.^{46–48} The localization of BPI in primary granules implies therefore that BPI is synthesized at or around the promyelocyte stage²⁸ and before the synthesis of secondary granule proteins such as lactoferrin. It is fitting, therefore, that BPI⁺/lactoferrin[−] precursor cells in bone marrow stain most intensely for BPI (Fig 3) because it would be expected that the accumulation of BPI is limited to the period of assembly of the primary granules.

*HL-60 cells ($2 \times 10^5/\text{mL}$) were incubated for four days in medium containing the indicated supplement. After washing the cells in unsupplemented medium, the BPI content was measured. Results shown represent the mean ($\pm$ SEM, where indicated) of two or more independent determinations.

†Differentiation induced during treatment; numbers in parenthesis indicate the percentage of cells (range) displaying differentiated characteristics (see Materials and Methods).

‡At four days, cell densities in untreated and DMSO-treated cultures were identical ($10^6/\text{mL}$). DMSO treatment caused a reduction in the cellular content of myeloperoxidase: immunofluorescence, reduced from 81% to 37% bright staining; RIA, reduced from 29 to 12 $\mu\text{g}/\text{mg}$ cell protein.

with dilution of their contents during subsequent cell divisions.^{28,42} The fact that earlier myeloid precursors (myeloblasts) either in culture or in blood of patients with myeloid leukemia in blast crisis do not contain detectable BPI also fits the prediction.

Whether or not all primary granule proteins are synthesized at the same time is unknown. Some subcellular fractionation studies have revealed heterogeneity within putative primary granule fractions.^{44,45,49} HL-60 cells are rich in myeloperoxidase but contain relatively little BPI and also subnormal amounts of other primary granule proteins.^{34,38} The enrichment of BPI in an apparently more mature subpopulation (FcR + Y201–,^{18,50,51} Table 4) of uninduced cells together with the increase in the BPI content and decrease in the myeloperoxidase content that accompany further differentiation of HL-60 cells (induced by DMSO) may mean that in these cells synthesis of BPI follows that of myeloperoxidase. Such dissociation may be an abnormal feature of this leukemic cell line. However, these observations may also represent normal aspects of the biogenesis of primary granules. Because myeloperoxidase, unlike BPI, is present in monocytes as well as neutrophils,⁵² synthesis of myeloperoxidase may commence in a precursor cell capable of following either the neutrophilic or the monocytic paths,^{53,54} whereas synthesis of a neutrophil-specific protein such as BPI would not begin until the cell becomes committed to the neutrophilic lineage. The majority of HL-60 cells,

which are capable of differentiating in either a granulocytic or monocytic direction,^{53–55} may represent cells just before commitment when the dissociation of the accumulation of myeloperoxidase and BPI is clearly manifested. Because of the uncertainties concerning the fidelity of differentiation of malignant cells in culture, verification of these concepts must await similar studies on normal bone marrow cells.

That production of BPI is apparently limited to cells of the neutrophil lineage may reflect both the strict target cell specificity of this antibacterial protein^{3,6,7} and the predominant role of the neutrophil in host defense against BPI-sensitive gram-negative bacterial species.^{3,56} A comparison of the structural and functional properties of BPI isolated from human and rabbit polymorphonuclear leukocytes has shown that BPI is a highly conserved cytotoxic protein,^{3,6,7,57} which is consistent with the view that its exclusive production by the highly specialized neutrophil signifies an important antibacterial function.

ACKNOWLEDGMENT

We gratefully acknowledge the generosity of Drs Mary B. Todd in providing murine monoclonal antibody Y201, Tor Olofsson in performing rosetting assays, Bruce Bank in obtaining bone marrow, and Peter Elsbach in many helpful discussions and critical readings of this manuscript. We also wish to thank Ingrid Gartner for her excellent technical assistance and Drs Jan Vilcek and Jack Hiller for providing cells from nonleukemic cell lines.

Dipyridamole Stimulates Urokinase Production and Suppresses Procoagulant Activity of Rabbit Alveolar Macrophages: A Possible Mechanism of Antithrombotic Action

By Jeffrey D. Hasday and Robert G. Sitrin

Dipyridamole, an inhibitor of platelet aggregation, has been shown to have beneficial effects in disorders characterized by extravascular fibrin deposition. Mononuclear phagocytes are present in extravascular sites and are capable of expressing both plasminogen activator and procoagulant activities, which suggests these cells play a central role in extravascular fibrin turnover. We therefore sought to determine whether dipyridamole affects the expression of plasminogen activator and procoagulant activities by rabbit alveolar macrophages cultured *in vitro*. We found that dipyridamole (10 to 100 $\mu\text{mol/L}$) caused increases in both cell-associated and released plasminogen activator activity, which reached levels of 240% ($P < .05$) and 543% ($P < .01$) of controls, respectively. In contrast, dipyridamole decreased the cell-associated procoagulant activity of alveolar macrophages to as little as 21.3% of controls ($P < .01$). Similar effects were seen in cells cotreated with lymphokines. The procoagulant activity expressed by

these cells functioned as a tissue thromboplastin. The plasminogen activator of control and treated cells was a urokinase as determined by molecular weight characteristics (50 kilodaltons) and by antibody neutralization profiles using polyclonal antibodies against human urokinase and tissue plasminogen activator. These effects of dipyridamole could not be duplicated by structurally dissimilar agents sharing some of the pharmacological actions of dipyridamole; however, two pyrimidopyrimidine compounds structurally similar to dipyridamole effectively mimicked the effects on both procoagulant and plasminogen activator activities. We conclude that dipyridamole may have antithrombotic effects by directly modulating the role of mononuclear phagocytes in fibrin turnover. Thus, dipyridamole may be useful in situations where extravascular fibrin deposition is important to the pathogenesis of tissue injury and repair.

© 1987 by Grune & Stratton, Inc.

DIPYRIDAMOLE is a pyrimidopyrimidine compound widely used in treating thrombotic disease because of its actions as a platelet antiaggregant and vasodilator.¹⁻³ In addition, dipyridamole has been used successfully either singly or in combined therapy for glomerulonephritis^{4,5} and in animal models of glomerulonephritis and disseminated intravascular coagulation.^{6,7} These diseases are characterized histologically by extravascular fibrin deposition as well as intravascular platelet-fibrin thrombi.^{8,9} However, it is not clear how dipyridamole may also have its antithrombotic effects in the extravascular space where platelet aggregation and altered blood flow may not be the prime determinants of fibrin deposition.

Mononuclear phagocytes express procoagulant activity mainly by producing a tissue thromboplastin that activates the extrinsic coagulation pathway.^{10,11} These cells may also contribute to fibrinolysis by producing a plasminogen activator¹² or plasminogen-independent enzymes.^{13,14} We have previously demonstrated that rabbit alveolar macrophages produce both tissue thromboplastin and plasminogen activator activities.^{15,16} Since mononuclear phagocytes are often abun-

dant at sites of inflammation, they may be important cellular mediators of tissue deposition and clearance of fibrin. Therefore, in this study we sought to determine whether dipyridamole can directly affect macrophage expression of procoagulant or plasminogen activator activities. Such an effect would offer a potential explanation for the modulation by dipyridamole of extravascular fibrin turnover in inflammatory foci.

MATERIALS AND METHODS

Animals. Normal male New Zealand white rabbits (1.5 to 2 kg) were given routine care in the Unit for Laboratory Animal Medicine, University of Michigan Medical Center.

Bronchoalveolar lavage. Rabbits were sacrificed by intravenous injection of pentobarbital and exsanguinated prior to lavage. The trachea was cannulated, and the lungs were lavaged with 35-mL aliquots of Dulbecco's calcium and magnesium-free phosphate-buffered saline at 37 °C (PBS; GIBCO, Grand Island, NY) until a return of 300 mL was obtained. Cells were collected by centrifugation and resuspended in 110 mmol/L Tris buffer in 100 mmol/L NaCl (pH 7.0) for two minutes to lyse contaminating erythrocytes. The cells were then washed three times in serum-free culture medium consisting of RPMI 1640 (GIBCO) containing penicillin (100 U/mL), streptomycin (100 $\mu\text{g/mL}$), gentamicin (100 $\mu\text{g/mL}$), polymyxin B (100 U/mL), and lactalbumin hydrolysate (0.2%; GIBCO) and counted with a hemocytometer.

Preparation of additives. Dipyridamole (Sigma Chemical Co, St Louis) and related additives were freshly dissolved in 95% ethyl alcohol to 10 mmol/L and further diluted in culture medium. The final concentration of ethyl alcohol in cell cultures did not exceed 1% and was found to alter neither cell viability nor expression of procoagulant and plasminogen activator activities (data not shown).

Lymphocyte-conditioned medium (LCM) was used as a crude source of lymphokines. Lymphocyte suspensions were prepared from paraortic lymph nodes as previously described.^{16,17} The cell suspensions (>95% lymphocytes) were incubated for 48 hours at 5×10^6 cells/mL in medium containing concanavalin A bound to Sepharose 4B beads (5 $\mu\text{g/mL}$ ConA, Pharmacia Fine Chemicals, Piscataway, NJ). The LCM was then centrifuged to remove cells and ConA-

Sepharose, sterilized by filtration, and stored at -70°C . Preliminary data indicated that a 1:8 dilution of LCM was optimal, and one such preparation was used in these experiments.

Cell culture. One million cells were dispensed in 1 mL of culture medium and incubated in duplicate in sterile 12×75 -mm polypropylene tubes for 24 hours at 37°C in 5% CO_2 -enriched air. Dipyridamole and other additives were included in the culture medium for the entire incubation period as indicated. Following incubation, the cells were collected by centrifugation and resuspended in fresh medium. Cell suspensions and incubation media were stored at -20°C prior to assay.

Procoagulant assay. The cells were lysed by two cycles of freeze-thawing followed by sonication. Preliminary experiments showed that the majority of the procoagulant activity remained cell associated *in vitro* because only minimal activity was found in the culture supernatants. None of the interventions tested caused a significant release of procoagulant activity into the incubation medium, thus indicating that modulation of procoagulant activity was adequately reflected by changes in the lysate activity. Accordingly, only cell lysates were routinely measured for procoagulant activity.

Procoagulant activity was assayed using a one-stage coagulation assay.¹⁶ One hundred microliters of test material was mixed with an equal volume of 25 mmol/L CaCl_2 at 37°C . Citrated normal rabbit plasma (100 μL) was then added, and the time elapsed until fibrin formation was measured with an automated coagulation timer (BBL Fibrosystem, Cockeysville, MD). Coagulation times of duplicate assays were reproducible within 12% over the range of activities encountered in this study. Standard curves were derived from serial dilutions of macrophage lysate by using a log-log plot of lysate concentration and the resultant coagulation time.¹⁶ Like identical assays using rabbit brain tissue thromboplastin (Sigma), these standards were linear for coagulation times ranging approximately from 20 to 260 seconds. Coagulation times could then be converted to arbitrary units of procoagulant activity to calculate the percent change from baseline activity induced by the various interventions.

To determine the mechanism of action of the procoagulant, samples were tested in coagulation assays using plasmas congenitally deficient in factors VIII, VII, or X (George King Bio-Medical, Overland Park, KS). In addition, the samples were pretreated with phospholipase C (Sigma), 0.05 $\mu\text{g}/\text{mL}$ for 30 minutes at 37°C because inactivation of procoagulant activity by this enzyme is indicative of tissue thromboplastin activity.¹¹

Plasminogen activator assay. Incubation media and cell lysates were assayed for plasminogen activator activity using a modification of the ^{125}I -fibrin plate assay of Unkeless et al.¹² Fibrin plates were prepared by adding to 16-mm plastic culture wells 60 μg of purified human fibrinogen (KABI, Stockholm, Sweden) containing 2×10^5 cpm ^{125}I -labeled fibrinogen (Amersham Corp, Arlington Heights, IL) and drying the plates at 37°C . The wells were then incubated with 5% acid-treated fetal bovine serum (GIBCO) to convert the fibrinogen to fibrin and then washed thoroughly with 0.1 mol/L Tris buffer (pH 8.1) prior to use. Plasminogen was prepared from outdated human plasma by lysine-Sepharose affinity chromatography (Pharmacia) according to the method of Deutsch and Mertz¹⁸ and quantified by protein content.¹⁹ To inactivate contaminating plasmin, the plasminogen preparation was incubated with phenylmethane sulfonyl fluoride (1 mmol/L) for 16 hours at 4°C followed by extensive dialysis. The plasminogen concentration that produced the maximal fibrinolysis with a standard sample of plasminogen activator was used in all assays (2 to 6 $\mu\text{g}/\text{mL}$).

To assay for plasminogen activator activity, test materials were added in duplicate with either plasminogen or buffer to ^{125}I -fibrin-coated wells in a final volume of 1 mL. Following incubation for four hours at 37°C , an aliquot of incubation medium was then removed

and ^{125}I activity measured with a gamma counter. Control wells containing either plasminogen or buffer alone were also included in each assay. Plasminogen activator activity was calculated as the difference between ^{125}I release in wells containing test material with plasminogen and the largest control value. The net ^{125}I release was expressed as the percentage of maximal release achieved by trypsinizing the wells. The resultant percent lysis was translated into milli-Plough units (mPU) by using a standard curve generated from human urokinase (Calbiochem, La Jolla, CA). Plasminogen-independent fibrinolysis was negligible in all samples and accounted for less than 5% of the fibrinolysis seen in the presence of plasminogen.

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Culture supernatants from alveolar macrophages ($10^6/\text{mL}$) incubated for 24 hours in standard medium or medium containing dipyridamole (100 $\mu\text{mol}/\text{L}$) were concentrated 40-fold by pressure dialysis (Amicon Ultrafiltration System, Diaflo $\times$ PM10 membrane, Amicon Corp, Lexington, MA). Concentrated supernatants and standard samples of human urokinase and tissue plasminogen activator (tPA; American Diagnostica, Greenwich, CT) were treated with 10% SDS/8 mol/L urea. The samples were then subjected to electrophoresis at 20 mA on $60 \times 100 \times 0.4$ -mm gels of 11% polyacrylamide with 10% SDS in a Laemmli buffer system under nonreducing conditions.²⁰

Fibrin-agar zymography. Fibrin-agar indicator plates were created by pouring agarose (1.25%) containing fibrinogen (2 mg/mL), thrombin (Sigma; 0.06 National Institutes of Health U/mL), and plasminogen (5 $\mu\text{g}/\text{mL}$) onto glass slides.²¹ Following completion of electrophoresis, the polyacrylamide gels were washed sequentially in Triton X-100 (2.5%) and water in preparation for assay on the fibrin-agar plates. The gels were then layered over the indicator plates and incubated at 37°C for six to eight hours. The indicator plates were then stained with amido black, and the plasminogen activator activity was located by identifying the zones of lysis on the indicator plates.

Antibody neutralization. The plasminogen activator activities of control and dipyridamole-treated culture supernatants were characterized by neutralization profiles with antibodies against human urokinase and tPA. Immunoglobulin from antihuman urokinase goat serum (generously provided by G. Murano, PhD; Department of Biologicals, Food and Drug Administration, Bethesda, MD) was purified by diethyl aminoethyl chromatography and ammonium sulfate precipitation.²² Goat antihuman tPA immunoglobulin prepared in like fashion was purchased from American Diagnostica. Antibody concentrations were determined by the protein content.¹⁹ Test samples and the two plasminogen activator standards adjusted to equivalent activity were preincubated with a range of concentrations of antibody prior to the measurement of plasminogen activator activity. In these experiments, the plasminogen activator activity was measured using the two-stage spectrophotometric method of Coleman and Green.²³ The percent inhibition by antibody was calculated using standard curves for plasminogen activator activity generated for each sample.

Statistical analysis. For all dose-response curves, multiple comparisons with control groups were performed using Dunnett's test applied to a one-way analysis of variance.²⁴ Single comparisons were made using the unpaired two-tailed Student's *t* test.²⁴

RESULTS

Cell culture. The cell preparations used in these experiments were consistently more than 95% alveolar macrophages as described previously.¹⁵ In all cases, cell viability was greater than 95% prior to incubation as determined by trypan blue exclusion. Following incubation for 24 hours in

medium alone, the viability was $90\% \pm 7\%$ (mean $\pm$ SD). The viability was not significantly reduced by dipyridamole in concentrations ranging from $1 \mu\text{mol/L}$ ($90.1\% \pm 9.4\%$) to $50 \mu\text{mol/L}$ ($80\% \pm 15\%$).

The procoagulant activity of cells cultured in medium alone remained low over 24 hours (108.6 ± 15 seconds). Since augmented expression of procoagulant activity by these cells is a consistent response to low concentrations of endotoxin,¹⁵ this served as an internal control to indicate that the cells were not being subjected to significant background stimulation by endotoxin in the culture system.

Effects of dipyridamole on alveolar macrophage plasminogen activator activity. In control cultures incubated in standard medium alone, the plasminogen activator activity of cell lysates was $448 \pm 101 \text{ mPU}/10^6$ cells; in addition, $462 \pm 111 \text{ mPU/mL}$ was present in the incubation medium (mean $\pm$ SEM). Dipyridamole stimulated marked increases in the plasminogen activator activity released into the medium, which reached a maximum of 543% of control cultures ($P < .01$; Fig 1). There was also a significant increase in the activity of cell lysates, which reached 240% of the controls ($P < .05$), thus indicating that dipyridamole augmented the total expression of plasminogen activator rather than simply stimulating the release of intracellular stores of the enzyme into the culture media. Plasminogen activator activity of maximally stimulated cells ($50 \mu\text{mol/L}$ dipyridamole) was $1,132 \pm 322 \text{ mPU}/10^6$ cells in lysates and $1,619 \pm 774 \text{ mPU/mL}$ in media, both significantly increased from control values ($P < .05$).

Dipyridamole had no direct effect on plasminogen activator activity when mixed with cell lysates, thereby indicating that the drug did not activate an existing proenzyme. Finally, stimulation of plasminogen activator production was completely blocked by cycloheximide ($5 \mu\text{g/mL}$), which indicated a requirement for protein synthesis (not shown).

Fig 1. Effects of dipyridamole on the expression by rabbit alveolar macrophages of cell-associated and secreted plasminogen activator activities. Data are expressed as the percentage of values obtained from control cells maintained in parallel cultures without dipyridamole. The mean $\pm$ SEM of six to 14 experiments are shown. An asterisk indicates P value less than .01 (Dunnett's test). Dipyridamole caused a concentration-related stimulation in the plasminogen activator activity of both cell lysates and culture media.

Characterization of unstimulated and dipyridamole-stimulated plasminogen activator. Plasminogen activator activities of incubation media from control and dipyridamole-treated alveolar macrophages were significantly inhibited by antihuman urokinase antibody (Fig 2A). A human urokinase standard with equivalent activity was similarly inhibited by this antibody, but there was little cross-reactivity with human tPA. The anti-tPA antibody had only a slight neutralizing effect on the control media and none on media from dipyridamole-treated cells (Fig 2B). This was comparable to the effect of antibody on urokinase standard, whereas tPA was completely neutralized. These results indicate that the plasminogen activator of normal and dipyridamole-treated alveolar macrophages is a urokinase rather than a tPA.

SDS-PAGE analysis of incubation media from both control and dipyridamole-treated cells revealed a single band of plasminogen activator activity with a molecular weight of approximately 50 kilodaltons (kD) (Fig 3). A human urokinase standard demonstrated a major band of activity of 53 kD and a minor band of 32 kD, whereas human tPA produced a single band of 68 kD. Together with the antibody neutralization experiments, these results indicate that dipyridamole caused increased production of a single form of urokinase rather than stimulating production of a second protease with plasminogen activator activity.

Effects of dipyridamole on alveolar macrophage procoagulant activity. The procoagulant activities of cell lysates

Fig 2. Characterization of plasminogen activator by neutralization with antiurokinase (anti-UK) (A) and anti-tPA (B) antibodies. Incubation media from normal and dipyridamole (DP)-treated alveolar macrophages were studied along with commercially prepared urokinase and tPA to determine the percent inhibition by each antibody (see Materials and Methods). The data are expressed as the mean percent inhibition of four experiments. The antiurokinase antibody effectively suppressed the plasminogen activator activity of the urokinase standard and both incubation media but not tPA (A). Likewise, the anti-tPA antibody effectively neutralized the tPA standard but neither urokinase nor the incubation media (B).

Fig 3. Molecular weight determination of rabbit alveolar macrophages plasminogen activator. Shown is the fibrin-agar indicator plate developed from an SDS-PAGE (see Materials and Methods). Human urokinase (lane 1) demonstrated a major band at 53 kD and a minor band at 32 kD, whereas human tPA produced a single band at 68 kD (lane 2). Incubation media from both dipyridamole-treated (lane 3) and untreated (lane 4) macrophages produced a single band of activity at 50 kD, virtually identical to the major band of human urokinase.

from control cultures were somewhat variable, but dipyridamole consistently and significantly decreased the expression of procoagulant activity in parallel cultures to as little as 21.3% of control values ($P < .01$; Fig 4A). The corresponding prolongation in coagulation time was also significant, increasing from 108.6 ± 15 seconds in controls to 190.1 ± 58.7 seconds in cells treated with $50 \mu\text{mol/L}$ dipyridamole ($P < .05$). To determine whether dipyridamole also suppressed the augmentation of procoagulant activity in response to an immunostimulant, alveolar macrophages were cocultured with dipyridamole and LCM. In these experiments, dipyridamole ($10 \mu\text{mol/L}$ and $100 \mu\text{mol/L}$) also decreased the procoagulant activity by as much as 83.3% (Fig 4B). The coagulation times were prolonged from 66.8 ± 10.7 seconds (LCM alone) to 96.5 ± 15.7 seconds ($10 \mu\text{mol/L}$, $P < .01$) and 171.3 ± 23.2 seconds ($100 \mu\text{mol/L}$, $P < .01$). Additional experiments verified that dipyridamole had similar suppressive effects on the procoagulant activity expressed by suspensions of intact cells (not shown).

Dipyridamole had no direct effect on the coagulation assay. Second, the loss of procoagulant activity in dipyridamole-treated cells was not affected by incorporating excess phospholipid (rabbit brain cephalin; Sigma) in the assay system, which suggests that the drug did not simply alter the phospholipid content of the lysates. Finally, in mixing experiments the addition of lysates of dipyridamole-treated cells lacking detectable procoagulant activity did not inhibit the activity of lysates of control cells, which indicates that

Fig 4. Effects of dipyridamole on the expression of procoagulant activity by unstimulated (A) and LCM-stimulated rabbit alveolar macrophages (B). Activities are expressed as the percentage of values obtained from control cells lacking dipyridamole; the mean $\pm$ SEM of six to 14 experiments are shown. An asterisk indicates a P value less than .01 (Dunnett's test). Dipyridamole caused a concentration-dependent suppression of procoagulant activity by both unstimulated and LCM-stimulated alveolar macrophages.

dipyridamole did not stimulate the expression of an inhibitor of procoagulant activity. The procoagulant activity of both untreated and dipyridamole-treated cell lysates functioned as tissue thromboplastin.¹⁶ This was demonstrated by a loss of procoagulant function in plasmas deficient in factors VII or X but not VIII (not shown). In addition, procoagulant activity was inactivated by pretreatment by phospholipase C, which inactivates tissue thromboplastin but not other coagulation factors.¹¹

Mechanism of action of dipyridamole. Experiments were performed to determine the mechanisms by which dipyridamole modulates expression of macrophage procoagulant and plasminogen activator activities. The effects of dipyridamole were (1) compared with those of structurally unrelated compounds sharing at least one of the known pharmacological actions of dipyridamole, (2) examined in the presence of agents that antagonize specific actions of dipyridamole, and (3) compared with those of structurally related pyrimidopyrimidines.

Dipyridamole is known to alter production and cellular responses to various arachidonic acid metabolites.²⁵ To deter-

mine whether dipyridamole acts through mechanisms involving arachidonic acid metabolism, alveolar macrophages were cotreated with dipyridamole, 100 $\mu\text{mol/L}$, and indomethacin, 1 $\mu\text{mol/L}$, a potent cyclooxygenase inhibitor. The addition of indomethacin did not alter the effects of dipyridamole on the expression of either procoagulant or plasminogen activator activities (Fig 5A). Further, we have demonstrated that neither exogenous arachidonic acid metabolites nor cyclooxygenase/lipoxygenase inhibitors could mimic the effects of dipyridamole on these macrophage functions (Hasday and Sitrin, manuscript submitted), thereby indicating that arachidonic acid metabolites are not directly involved in the action of dipyridamole.

Dipyridamole is known to inhibit the transport of adenosine across plasma membranes, which leads to extracellular accumulation of adenosine and increased stimulation of plasma membrane adenosine receptors.²⁶ To determine whether dipyridamole modulates procoagulant and plasminogen activator activities by blocking adenosine transport, we cotreated alveolar macrophages with dipyridamole and theophylline, 100 $\mu\text{mol/L}$, which blocks the adenosine receptor.²⁷ The addition of theophylline did not block the effects of dipyridamole (Fig 5B). Second, we compared cells treated with dipyridamole with those treated with nitrobenzylthioinosine (NBTI, 0.1 to 100 $\mu\text{mol/L}$), another inhibitor of adenosine transport.²⁶ NBTI did not mimic the effects of dipyridamole, but caused only moderate suppression of procoagulant activity, and had no effect on the plasminogen activator activity (Fig 5B). These results indicate that the action of dipyridamole is not based on the inhibition of adenosine transport across cell membranes.

Dipyridamole is known to inhibit cyclic adenosine monophosphate (AMP)-phosphodiesterase.²⁸ To determine whether this action pertains to its effects on procoagulant and plasminogen activator expression, we compared the

effects of dipyridamole with those of other phosphodiesterase inhibitors, papaverine (10 $\mu\text{mol/L}$) and methylisobutylxanthine (MIX, 100 $\mu\text{mol/L}$). In contrast to the effects of dipyridamole, papaverine significantly inhibited both plasminogen activator and procoagulant activities by 56.5% ($P < .01$) and 45% ($P < .05$), respectively (Fig 5C). MIX inhibited plasminogen activator activity by 69% ($P < .01$) but had no significant effect on procoagulant activity. These results indicate that inhibition of cyclic AMP phosphodiesterase cannot fully explain the actions of dipyridamole. The mechanism of action of these phosphodiesterase inhibitors is likewise unclear. We have recently shown that dibutyryl cyclic AMP suppresses plasminogen activator secretion but not cell-associated procoagulant activity, thus indicating that the effects of papaverine and MIX cannot be explained solely by a global increase in intracellular levels of cyclic AMP (Hasday and Sitrin, manuscript submitted).

Finally, experiments were performed to investigate whether the effects of dipyridamole were shared by other pyrimidopyrimidines. Alveolar macrophages were treated with *RXRA-85* (4-[1-oxidothiomorpholino]-8-[2-phenylethylthio]-2-piperizino-pyrimido/5, 4-D/pyrimidine) and *RE-102* (3,6-dimorpholino-8[bis-(2-hydroxypropyl)-amino-2-phenyl-pyrimido-(5,4-B)pyrize], two structural analogues of dipyridamole kindly provided by the Boehringer-Ingelheim Co (FR Germany). The effects of optimal concentrations of these compounds on the expression of procoagulant and plasminogen activator activities are shown in Fig 6. Both *RXRA-85* (10 $\mu\text{mol/L}$) and *RE-102* (100 $\mu\text{mol/L}$) significantly inhibited expression of procoagulant activity (69.7% and 92.3% respectively, $P < 0.01$). In addition, the release of plasminogen activator into culture media was markedly stimulated (325% and 486% respectively, $P < 0.01$), effectively duplicating the effects of dipyridamole.

Fig 5. Investigation of the mechanism by which alveolar macrophages modulate procoagulant and plasminogen activator activities. Data are expressed as in Fig 1. (A) The actions of dipyridamole (DP, 100 $\mu\text{mol/L}$) were unaffected by cotreatment with indomethacin (INDO, 1 $\mu\text{mol/L}$). (B) The effects of dipyridamole were not altered by cotreatment with theophylline (THEO, 100 $\mu\text{mol/L}$), which blocks plasma membrane adenosine receptors. Likewise, these effects were not duplicated by treating macrophages with NBTI (10 $\mu\text{mol/L}$), which also blocks adenosine transport across plasma membranes. (C) The effects of dipyridamole could not be duplicated by two other phosphodiesterase inhibitors, papaverine (PAP, 10 $\mu\text{mol/L}$) and methylisobutylxanthine (MIX, 100 $\mu\text{mol/L}$). □, Procoagulant; ▨, PLG activator.

Fig 6. Effects of structural analogues of dipyridamole on alveolar macrophage procoagulant and plasminogen activator activities. Optimal concentrations of the agents are compared and data are expressed as in Fig 1. The effects of dipyridamole (DP, 50 μ mol/L) were duplicated by RXRA-85 (10 μ mol/L) and RE-102 (100 μ mol/L). $\square$, Procoagulant; ▨ , PLG activator.

DISCUSSION

The close association between inflammatory reactions and activation of the coagulation and fibrinolytic systems is well recognized.^{8,9,29-31} The clinical manifestations of these interrelationships include disseminated intravascular coagulation and localized formation of intravascular fibrin-platelet thrombi.^{29,31} In addition, fibrin deposition outside the vascular space is prominent in many inflammatory states such as cutaneous hypersensitivity, glomerulonephritis, and acute lung injury.^{8,30,31} Various methods of anticoagulation have suppressive effects on cutaneous hypersensitivity and glomerulonephritis, which suggests that products of coagulation may intensify inflammation.^{32,33} In vitro experiments have demonstrated that fibrinogen-related products are leukocyte chemotaxins, impair macrophage mobility, and induce microvascular permeability.³⁴⁻³⁶

Although the factors controlling extravascular fibrin turnover are not well elucidated, there is considerable evidence to suggest that mononuclear phagocytes are central to this process. These cells can directly promote coagulation by elaborating tissue thromboplastin and other coagulation factors as well as mediating fibrinolysis by producing plasminogen activator or fibrinolytic enzymes.¹⁰⁻¹⁷ Both tissue thromboplastin and plasminogen activator activities can be stimulated in vitro by many stimuli relevant to inflammation including lymphokines and bacterial lipopolysaccharides.¹⁰⁻¹⁷ Recent studies have suggested that macrophage-derived procoagulant activity contributes to local fibrin deposition in experimental glomerulonephritis, thereby supporting the potential importance of these activities in vivo.³⁷ Further, Chapman et al have demonstrated abnormal expression of procoagulant and plasminogen activator activities by alveolar macrophages from some patients with interstitial lung disease.³⁸ Currently, there are few options for pharmacologically manipulating the effect of macrophages on fibrin deposition and clearance. Glucocorticosteroids, indomethacin, Coumadin, and prostaglandin E modify expression of procoagulant or plasminogen activator activities in vitro, but no other agents potentially applicable to in vivo use have been identified.^{32,39-41}

Several studies have demonstrated beneficial effects of dipyridamole in glomerulonephritis and attributed these to its actions as an inhibitor of platelet function.⁴⁻⁶ Since the crescentic fibrin deposition seen in an animal model appears to be caused by infiltrating macrophages,³⁷ we sought to determine whether dipyridamole directly modulates the expression of procoagulant or fibrinolytic activities of mononuclear phagocytes. Using normal rabbit alveolar macrophages, we found that dipyridamole had profound effects on the expression of both activities in vitro because expression of tissue thromboplastin activity was suppressed by over 80% whereas the concurrent release of plasminogen activator was increased by more than fivefold. The suppression of tissue thromboplastin activity occurred by decreased cellular expression of this factor rather than by stimulating production of an inhibitory protein or by directly affecting the extrinsic coagulation pathway. Likewise, dipyridamole directly stimulated cellular production of plasminogen activator rather than causing the release of the enzyme from intracellular stores or by activating a preexisting proenzyme. The plasminogen activator was found to be a single protein with molecular weight and immunologic characteristics of urokinase. The mechanisms underlying these actions of dipyridamole remain undefined. We determined that structurally unrelated compounds sharing at least one of the well-recognized pharmacological actions of dipyridamole, namely cyclic AMP-phosphodiesterase inhibition,²⁸ blockade of purine transport across plasma membranes,²⁶ and alteration of arachidonic acid metabolism²⁵ could not reproduce both these effects. However, two other structurally related pyrimidopyrimidines were roughly equipotent in their effects on both tissue thromboplastin and urokinase activities.

Further studies are certainly necessary to determine whether dipyridamole has comparable effects on mononuclear phagocytes in vivo. However, the potential biologic relevance of the findings reported here is supported by the observation that dipyridamole affected both activities in vitro at concentrations ranging from 10 to 25 μ mol/L. Plasma concentrations in excess of 10 μ mol/L can be achieved in some human subjects with the peak effect of a single 75-mg dose, and considerably higher doses have been given safely.^{4,42} It also remains to be seen whether prolonged administration in vivo can achieve comparable effects even with lower ambient concentrations of this drug.

The results of this study suggest several important areas for future investigations. First, it will be necessary to explore the possibility that dipyridamole and related compounds can be therapeutic in inflammatory disorders by preventing fibrin from accumulating in tissues. These studies should also better define the importance of macrophage-directed fibrin turnover in the pathogenesis of inflammation and healing. One potential advantage to this approach is that fibrin deposition may be selectively suppressed in injured tissue where macrophages have accumulated without inducing a severe generalized hemostatic defect. Second, the possibility is raised that dipyridamole may have other striking effects on macrophage functions beyond the two activi-

ties reported here, thereby suggesting that the pyrimidopyrimidines represent a new class of pharmacological agents for modulating mononuclear phagocyte function in inflammatory diseases in vivo. Further supporting this hypothesis are limited studies demonstrating that dipyridamole inhibits lymphoproliferation and stimulates interferon secretion by leukocytes in vitro.^{43,44} Such investigations may also provide important new information on the mechanisms underlying the pharmacological actions of pyrimidopyrimidines as well as the expression of macrophage effector functions. Finally, these actions of dipyridamole may have important implications for investigations of atherosclerotic diseases. Prior studies have demonstrated that macrophages infiltrate atheromas and release factors that may contribute to their progression.⁴⁵ Moreover, dipyridamole has inhibited plaque formation in experimental atherosclerosis.⁴⁶ Given the current evidence for the role of thrombus formation in coronary artery occlusion and the widespread interest in thrombolytic

and anticoagulant therapies for management of myocardial ischemia,^{47,48} the possibility for pharmacologically suppressing some of the thrombogenic activity in atheromas while concurrently increasing local fibrinolysis certainly merits further investigation.

In summary, we have demonstrated that dipyridamole causes alveolar macrophages to decrease the expression of tissue thromboplastin activity while concurrently stimulating the production and release of urokinase. These combined actions suggest that dipyridamole may effectively prevent fibrin accumulation at sites of inflammation through its direct effects of mononuclear phagocytes.

Synergistic Action of Two Murine Monoclonal Antibodies That Inhibit ADP-Induced Platelet Aggregation Without Blocking Fibrinogen Binding

By Peter J. Newman, Rodger P. McEver, Mary P. Doers, and Thomas J. Kunicki

We have used two murine monoclonal antibodies, each directed against one component of the human platelet membrane glycoprotein (GP) IIb-IIIa complex, to examine further the molecular requirements for fibrinogen binding to the platelet surface and subsequent platelet-platelet cohesion (aggregation). Although neither AP3, which is directed against GPIIb, nor Tab, which is specific for GPIIb, were individually able to inhibit adenosine diphosphate (ADP)-induced fibrinogen binding, platelet aggregation, or secretion, the combination of AP3 and Tab completely abolished platelet aggregation and the release reaction. Unexpectedly, this synergistic inhibition of platelet-platelet cohesion occurred in the presence of apparently normal fibrinogen binding. Both the number of fibrinogen molecules bound and the dissociation constant for fibrinogen binding remained essentially unchanged in the presence of

these two antibodies. Inhibition of aggregation was dependent upon the divalency of both AP3 and Tab because substitution of Fab fragments of either antibody for the intact IgG resulted in a complete restoration of both aggregation and secretion. In contrast to ADP induction, thrombin-activated platelets neither aggregated nor bound fibrinogen in the presence of AP3 plus Tab but were fully capable of secretion, which illustrated the multiple mechanisms by which the platelet surface can respond to different agonists. These data demonstrate that fibrinogen binding to the platelet surface alone is not sufficient to support platelet-platelet cohesion and that an additional post-fibrinogen-binding event(s) that is inhibitable by these two monoclonal antibodies may be required.

FOLLOWING BLOOD VESSEL injury, platelets rapidly adhere to the exposed subendothelium, release the contents of their granules, and form platelet aggregates that are responsible for the primary arrest of bleeding. Platelet plasma membrane glycoproteins mediate many of these events and serve as receptors for several physiological agonists and cofactors important in this hemostatic process including thrombin, collagen, von Willebrand factor (vWf) and fibrinogen.¹⁻³ There is considerable evidence that platelet-platelet cohesion (aggregation) is mediated by the binding of fibrinogen, an elongated, symmetrical molecule of 340,000 daltons,⁴ to adjacent platelets. Studies in a number of laboratories have demonstrated that adenosine diphosphate (ADP)^{5,6} thrombin,^{7,8} epinephrine,^{5,9} and certain stable prostaglandin analogues¹⁰ induce platelet cohesion by exposing fibrinogen receptors on the platelet surface. Fibrinogen then binds to activated platelets via a heterodimer receptor complex composed of plasma membrane glycoproteins (GP) GPIIb and IIIa (reduced molecular weights of 130,000 and 100,000 daltons, respectively). Evidence for this is derived, in part, from studies on individuals with the congenital bleeding

disorder Glanzmann's thrombasthenia. The platelets of these patients are deficient in these two membrane glycoproteins,^{11,12} and consequently their platelets fail both to bind fibrinogen and to aggregate normally.^{5,13,14} In addition, the binding to normal platelets of murine monoclonal antibodies specific for the intact GPIIb-IIIa complex induces a thrombasthenic condition by inhibiting both fibrinogen binding and subsequent aggregation.¹⁵⁻¹⁸ Together, these data have been taken to indicate that platelet aggregation is an inevitable consequence of fibrinogen binding to its platelet surface receptor.

We have previously reported the production and characterization of monoclonal antibodies specific for components of the platelet fibrinogen receptor: Tab, which is specific for GPIIb¹⁶; AP3, which is specific for GPIIa¹⁹; and AP2, a monoclonal antibody reactive only with the intact GPIIb-IIIa complex.¹⁵ When bound to the platelet surface, AP2 blocks both fibrinogen binding and platelet aggregation induced by ADP, thrombin, arachidonic acid, or collagen. Unlike AP2, neither Tab nor AP3 are able to block the binding of fibrinogen to the platelet surface or inhibit platelet aggregation, presumably because the epitopes recognized by these two antibodies are not close enough to the fibrinogen binding site to inhibit its interaction with the GPIIb-IIIa complex. Though only Tab and AP3 react with both dissociated as well as complexed GPIIb and GPIIa, all three antibodies react with 40,000 to 50,000 sites at saturation on the platelet surface, thus supporting the concept that GPIIb and GPIIa normally exist complexed in a 1:1 stoichiometry in the plasma membrane of intact, nonactivated platelets.¹⁹ In this report, we describe a synergistic effect of AP3 and Tab on ADP-induced platelet aggregation that provides new insights into the molecular requirements for fibrinogen binding and the process of platelet aggregation.

MATERIALS AND METHODS

Preparation of washed platelet suspensions. Human platelets were isolated from whole blood using a modification of the method of Patscheke.²⁰ Briefly, 43 mL of venous blood obtained from healthy volunteer donors was anticoagulated with 7 mL of acid citrate

dextrose (ACD, National Institutes of Health formula A). Following the preparation of platelet-rich plasma (PRP), prostaglandin E_1 , (PGE_1) and apyrase (Sigma Chemical Co, St Louis; Grade III) were added to the platelets to final concentrations of 20 nmol/L and 25 μ g/mL, respectively. ACD was then added in the ratio of one part ACD to nine parts PRP to further acidify the PRP. Platelets were washed three times by differential centrifugation at 1,200 g in Wash buffer (103 mmol/L NaCl, 36 mmol/L citric acid, 5 mmol/L dextrose, 5 mmol/L KCl, 2 mmol/L $CaCl_2$, 1 mmol/L $MgCl_2$, 0.35 mg/mL bovine serum albumin (BSA), 20 nmol/L PGE_1 , and 25 μ g/mL apyrase, pH 6.5) and resuspended into Resuspension buffer (137 mmol/L NaCl, 2 mmol/L KCl, 0.3 mmol/L NaH_2PO_4 , 2 mmol/L $CaCl_2$, 1 mmol/L $MgCl_2$, 5.5 mmol/L dextrose, 5 mmol/L HEPES, 12 mmol/L $NaHCO_3$, and 0.35 BSA, pH 7.4) before use. Both Wash and Resuspension buffers were used for a maximum of 1 week. Platelets prepared in this manner retained the ability to aggregate and bind fibrinogen for at least four hours.

Proteins. The purification and properties of the murine monoclonal antibodies AP1, AP2, AP3, and Tab have been previously described^{15,16,18,21} and are described in Table 1. AP1 is specific for human platelet membrane GPIIb, AP2 is specific for the GPIIb-IIIa complex, AP3 has specificity for only GPIIIa, and Tab is specific for only GPIIb. Monoclonal IgG used in these studies was purified by sequential ammonium sulfate fractionation and diethyl aminoethyl (DEAE)-cellulose chromatography or by caprylic acid precipitation as described previously.^{19,22} Fab fragments of AP3 and Tab were produced by digestion for five hours at 37 °C with immobilized papain (Pierce Chemical Co, Rockford IL) in a buffer containing 50 mmol/L NaH_2PO_4 , 5 mmol/L EDTA, and 20 mmol/L cysteine, pH 6.5. Reaction products were alkylated for 30 minutes in the dark with 15 mmol/L iodoacetamide and dialyzed into 0.1 mol/L NaH_2PO_4 , pH 8.0. Fab fragments were separated from Fc fragments and undigested IgGs by chromatography through protein A-Sepharose (Pharmacia Fine Chemicals, Piscataway, NJ) and their purity assessed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under both reducing and nonreducing conditions. Chromatographically pure Peak 1 human fibrinogen, a kind gift from Dr D. Amrani, Mount Sinai Medical Center, Milwaukee, was shown to be free of contaminating vWf and fibronectin by both quantitative electroimmunoassay and the inability to support ristocetin-induced platelet aggregation. Purified fibrinogen was approximately 95% clottable prior to labeling and greater than 90% clottable following radioiodination and storage.

Radioiodination of proteins in solution. Fibrinogen was radioiodinated by reacting 5 mg of protein with 0.3 mCi of carrier-free $Na^{125}I$ (New England Nuclear, Boston) for 15 minutes in the presence of insolubilized lactoperoxidase (Enzymobeads, Bio-Rad Laboratories, Richmond, CA) according to the manufacturer's directions. Fifty to 100 μ g of each monoclonal antibody was labeled with 1 mCi of ^{125}I in a similar fashion. Following iodination, unbound ^{125}I was removed from the reaction mixture by gel filtration through Sephadex G-25 equilibrated in resuspension buffer. The specific activity of the fibrinogen was approximately 100 cpm/ng and approximately 1,000 cpm/ng for each of the monoclonal antibodies.

Radioiodinated antibodies were stored in small aliquots at -80 °C. Labeled fibrinogen was stored at 4 °C and used within 1 week.

Platelet aggregometry. Aggregometry was performed in a Bio-Data PAP-4 four-channel aggregometer (Bio-Data Corp, Horsham, PA) at 37 °C with a stirring rate of 1,200 rpm. ADP was used to induce aggregation at concentrations of 5, 10, and 20 μ mol/L. Thrombin and epinephrine were used at concentrations of 0.1 to 1.0 U/mL and 2.2 μ mol/L, respectively. The effects of monoclonal antibody binding on platelet aggregation were measured by preincubating washed platelets with the indicated concentrations of antibody for five minutes at 37 °C prior to the induction of aggregation. Lumiaggregometry was performed using a Chrono-Log Model 400 Lumiaggregometer. The luciferase-luciferin reagent was also from Chrono-Log Corp (Havertown, PA).

Quantitative fibrinogen binding analysis. Binding assays were performed in triplicate at room temperature (except where indicated) using washed platelets prepared as described. 1.5-milliliter polypropylene tubes precoat with 1 mL BSA dissolved in Resuspension buffer were used in all phases of the experiment. For the ADP-induced fibrinogen binding experiments, ^{125}I -fibrinogen was added at varying concentrations to washed platelets in Resuspension buffer such that the final platelet concentration was 1×10^8 /mL in a reaction volume of 200 μ L. Preliminary experiments (not shown) established that normal ADP-induced fibrinogen binding was saturable and required the presence of calcium. Monoclonal antibodies in the form of intact IgG or Fab fragments were added either prior to or simultaneous with the addition of fibrinogen and allowed to incubate with the platelets for five to ten minutes before the addition of ADP. Binding was initiated by addition of ADP to final concentrations ranging from 3.3 to 33 μ mol/L. The reaction was terminated five minutes later by centrifugation (12,000 g for three minutes) of a 75- μ L aliquot over 400 μ L of 15% sucrose dissolved in Resuspension buffer. After removing the supernatant, the centrifuge tube tips were amputated and the bound radioactivity determined in a gamma counter. Thrombin-induced fibrinogen binding was induced by incubating platelets that had been preincubated with antibody for ten minutes with 0.1 U/mL of α -thrombin (a gift of Dr Richard A. Marlar, The Blood Center of Southeastern Wisconsin, Milwaukee) for five minutes at 25 °C. Thrombin was inactivated by the addition of hirudin (0.2 U/mL) for five minutes, and then ^{125}I -fibrinogen was added to initiate binding. The reaction was terminated 15 minutes later by centrifugation and aspiration, as described above. In selected experiments, monoclonal antibodies or their Fab fragments were added following rather than prior to thrombin/hirudin activation of platelets. The bound radioactivity was pure fibrinogen, as determined by SDS-PAGE and autoradiographic analysis of the solubilized pellets. The total radioactivity was determined by counting an identical 75- μ L aliquot of each reaction mixture. Nonspecific binding was determined in parallel tubes containing 10 mmol/L EDTA, and this value was subtracted from the total bound counts per minute to yield specifically bound counts per minute. This value was shown to be comparable to nonspecific binding levels obtained in the presence of a 25-fold excess of unlabeled fibrinogen. Fibrinogen binding affinities and the maximum number of sites

Table 1. Murine Monoclonal Antibodies Specific for Human Platelet Membrane GPIIb and IIIa

Antibody	Specificity	No. Sites/Platelet	K_D (nmol/L)	Inhibition of Fibrinogen Binding	Inhibition of Platelet Aggregation	Reference
AP2	GPIIb-IIIa complex	54,000	0.64	Yes	Yes	15
AP3	GPIIIa	40,000	0.72	No	No	19
Tab	GPIIb	40,000	0.73	No	No	16
AP1	GPIIb	20-30,000	2.10	No	No	21

bound per platelet were calculated and analyzed using the weighted nonlinear least-squares curve fitting program LIGAND.²³ Objective statistical criteria (residual variance, F test) were used to evaluate the goodness of fit and to discriminate between models testing different classes of binding sites.

Measurement of β -thromboglobulin (β -TG) release. Platelets in PRP at a final concentration of 1×10^8 /mL were added to an aggregometer cuvette and incubated in an aggregometer at 37 °C for two minutes. Antibodies diluted in platelet-poor plasma (PPP) or PPP alone were added and incubated an additional ten minutes with stirring (1,000 rpm). Aggregation and release were induced by the addition of 20 μ mol/L ADP/2.2 μ mol/L epinephrine, and activation was allowed to proceed for 3.5 minutes, ie, the amount of time necessary to achieve maximal aggregation in those samples that were able to aggregate. PGE₁ was then added to the cuvette to a final concentration of 20 ng/mL to inhibit further activation and release that might occur as a result of subsequent handling. An 85- μ L aliquot was removed from the cuvette, and released β -TG was quantitated by using a standard radioimmunoassay kit (Amersham Corp, Arlington Heights, IL).

Competitive monoclonal antibody binding experiments. A quantity of 3.6 ng of radiolabeled monoclonal antibody was added to 6×10^6 platelets in the presence or absence of a 250-fold excess of the indicated unlabeled monoclonal antibody. This amount was predetermined to give the maximal inhibition of binding of an identical radioiodinated antibody. The volume was adjusted with PRP to 300 μ L to yield a final platelet concentration of 2×10^7 /mL. Both labeled and unlabeled antibodies were added to the platelets at the same time to ensure equal opportunity for binding. After a 30-minute incubation at room temperature, the aliquots were removed, and the bound radioactivity was determined as described. Nonspecific binding varied from 3% to 9% for each of the monoclonal antibodies.

RESULTS

Binding of AP2, AP3, and Tab to intact human platelets. To investigate the spatial relationship of the binding sites of AP2, AP3, and Tab to the GPIIb-IIIa complex, we examined the ability of these three monoclonal antibodies to compete with each other for binding to the platelet surface. Unlabeled antibodies were added in saturating amounts in conjunction with subsaturating levels of either the same or different radioiodinated antibody, and the effects on the counts per minute bound were examined. This experimental design allowed us to conserve the amount of radioactive sample added to each tube without compromising the necessity of saturating the platelet surface with at least one of the antibodies to determine true competition. It was determined that the dissociation constants of the three monoclonal antibodies would not be a factor in performing the competition experiments since they each have similar affinities for the platelet surface (Table 1). Figure 1 shows a representative inhibition experiment using radiolabeled AP2 and competing levels of each of the other monoclonal antibodies. As can be seen, ¹²⁵I-AP2 binding was inhibited by excess unlabeled AP2 but not at all by either Tab or AP3. Of special importance is the observation that even the combination of saturating amounts of AP3 and Tab had no effect on the binding of subsaturating amounts of AP2. Similar experiments using radiolabeled AP3 or radiolabeled Tab (not shown) showed that the binding of each radiolabeled monoclonal antibody could only be effectively blocked by its

Fig 1. Simultaneous binding of AP3, AP2, and Tab to washed, intact human platelets. Radiolabeled AP2 (3.6 ng) was added to each tube in the presence or absence of a variable excess of the indicated unlabeled monoclonal antibody. The final volume was adjusted with PRP to 300 μ L to yield a platelet concentration of 2×10^7 /mL.

corresponding unlabeled antibody. In no instance was binding affected by the presence of saturating levels of the other two. Thus, these data indicate that the GPIIb-IIIa complex is able to accommodate the simultaneous binding of at least three different intact monoclonal IgG antibodies and that the epitopes recognized by AP2, AP3, and Tab are sufficiently distinct to permit cohabitation.

Effect of AP2, AP3, and Tab on ADP- or thrombin-induced platelet aggregation and secretion. We next examined the effects of AP3 and Tab, alone or in combination, on platelet aggregation. As shown in Fig 2, neither AP3 nor Tab alone inhibited ADP-induced shape change or aggregation, even at antibody doses as high as 40 μ g/mL. When the two antibodies were added together, however, platelet aggregation was completely inhibited, thereby mimicking the effect of AP2 alone. To see whether the effect of AP3 plus Tab was not merely to reduce the size of the platelet aggregate to a level that would not be recorded by the aggregometer (eg, from 10 to 4 or 5 platelets/aggregate), we verified by phase-contrast microscopy that platelets

Fig 2. Effect of AP2, AP3, or Tab on ADP-induced platelet aggregation. Washed platelets were resuspended to a concentration of 1×10^8 /mL and warmed to 37 °C. Ten micrograms of the indicated monoclonal antibody was then added and allowed to incubate with stirring for five minutes. Platelet aggregation was then induced by the sequential addition of purified Peak I fibrinogen to 200 μ g/mL and ADP to a final concentration of 10 μ mol/L. The addition of fibrinogen prior to the addition of antibody did not affect the outcome of the experiment.

remained monodispersed following ADP stimulation in the presence of either AP2 or the combination of AP3 plus Tab (not shown). In both cases, shape change was readily apparent, even in the absence of platelet-platelet interaction. Concentrations of ADP as high as 30 $\mu\text{mol/L}$ were unable to overcome the inhibitory effect of AP3 and Tab. The same results were obtained using ADP/epinephrine or thrombin (0.1 to 1.0 U/mL) as agonists. When AP3 was added simultaneously with the antiplatelet monoclonal antibody AP1 (specific for GPIb), platelets were able to aggregate fully regardless of the agonist used (data not shown). Similarly, the combination of Tab and AP1 also failed to inhibit aggregation. These results indicated that inhibition was specific for the combination of AP3 plus Tab and not due to overloading of the platelet surface with immunoglobulin. Tab plus AP3 blocked platelet aggregation in a dose-dependent manner, with half-maximal inhibition occurring at 4 $\mu\text{g/mL}$ of each antibody and complete inhibition occurring at 10 to 12 $\mu\text{g/mL}$ each.

The effects of AP3 and Tab, alone or in combination, on platelet secretion were examined in a lumiaggregometer by using the luciferin/luciferase system to measure the adenosine triphosphate (ATP) released from platelet dense granules. Platelets in PRP at a final concentration of $1 \times 10^8/\text{mL}$ were preincubated with antibodies or buffer for ten minutes at 37 °C. Platelet activation was induced by the addition of 10 $\mu\text{mol/L}$ ADP, 10 $\mu\text{mol/L}$ ADP/2.2 $\mu\text{mol/L}$ epinephrine, or 0.1 units of thrombin, and the effects on both aggregometry and ATP secretion were observed simultaneously. As expected, ADP-induced ATP release was dependent upon a prior primary aggregation response; ie, AP2 alone or AP3 plus Tab blocked primary aggregation and the subsequent release of ATP. In contrast, thrombin-induced ATP release, which precedes aggregation, was unaffected by all monoclonal antibodies tested, alone and in combination, which suggests that AP2 and AP3 plus Tab block ATP release mainly by inhibiting events that lead up to secretion and do not interfere with secretion per se. The results of these studies are summarized in Table 2.

We also examined the effect of AP3 plus Tab on ADP-induced α -granule secretion as measured by β -TG release. In two experiments, AP2 alone and AP3 plus Tab each inhib-

ited β -TG release by 77% and 68%, respectively, compared with control platelets preincubated with buffer alone rather than antibodies. If PGE₁ was added prior to the addition of agonist, β -TG release was completely blocked. Similarly, in the absence of both PGE₁ and ADP, no release occurred.

Effect of AP2, AP3, and Tab on ADP-induced fibrinogen binding. Since AP3 and Tab clearly bind to different epitopes than AP2 (Fig 1) yet together inhibit aggregation to a similar extent (Fig 2), we examined the effects of the combination of AP3 plus Tab on ADP-induced fibrinogen binding. As has been reported previously, AP2 inhibits platelet aggregation and fibrinogen binding to the platelet surface,¹⁵ whereas Tab alone¹⁶ and AP3 alone¹⁹ are without effect. We confirmed these observations, and our results are shown in the inset to Fig 3. Surprisingly, the combination of AP3 plus Tab, even at concentrations as high as 20 $\mu\text{g/mL}$ each, also failed to inhibit the binding of fibrinogen to platelets of all concentrations tested. As shown in Fig 3, the binding isotherm for fibrinogen interaction with the platelet in the presence of AP3 plus Tab is nearly superimposable with the binding curve generated in the absence of antibodies. This observation has been confirmed using platelets from seven different individuals. Aggregometry was always performed in parallel with fibrinogen-binding experiments, using identical reagents and antibody preparations to eliminate variations that might bias their comparison, and aggregation was always completely inhibited under conditions where fibrinogen binding was 100%.

To test whether fibrinogen might be bound abnormally in the presence of these two antibodies, quantitative analyses of several additional binding experiments were performed. Both the number of fibrinogen molecules bound at saturation and the affinity of fibrinogen for its platelet receptor were determined in the presence or absence of 20 $\mu\text{g/mL}$ each of AP3 and Tab. Scatchard plot analysis of the binding data yielded linear plots, with no evidence of cooperativity or multiple classes of receptor sites. The mean K_d for fibrinogen binding was calculated to be $0.52 \pm 0.14 \mu\text{mol/L}$ (mean $\pm$ SEM of three determinations using two different donors) in the absence of antibody and $0.32 \pm 0.06 \mu\text{mol/L}$ in the presence of saturating amounts of Tab and AP3. Similarly, no significant difference was observed in the number of

Table 2. Summary of the Effects of AP2, AP3, and Tab on Selected Platelet Functions

Agonist	Antibodies	Fibrinogen Binding	Percent Aggregation	Percent ATP Release	Shape Change
ADP	None	+	100	100	+

Fig 3. ADP-induced fibrinogen binding to intact platelets in the presence or absence of AP3 plus Tab. ^{125}I -fibrinogen was added in increasing concentrations to washed platelets ($1 \times 10^8/\text{mL}$) and allowed to incubate at 25°C for five minutes in the presence (○—○) or absence (●—●) of $20 \mu\text{g}/\text{mL}$ each of AP3 and Tab. Binding was induced by the addition of ADP to $10 \mu\text{mol}/\text{L}$. Nonspecific binding was subtracted as described in Materials and Methods. Values shown represent the specific fibrinogen binding from one typical analysis. (Inset) Histogram depicting the individual effects of AP2, AP3, Tab, and AP3 plus Tab on ADP-induced ^{125}I -fibrinogen binding. Platelets were at a $1 \times 10^8/\text{mL}$ and fibrinogen at a $200 \mu\text{g}/\text{mL}$ final concentration. All antibodies were at $10 \mu\text{g}/\text{mL}$ each. Binding was induced by the addition of ADP to $10 \mu\text{mol}/\text{L}$. c, control samples with no antibody. Note that AP3 plus Tab completely block platelet aggregation (Fig 2) without inhibiting fibrinogen binding.

fibrinogen molecules bound per platelet at saturation in the presence or absence of the two antibodies (Table 3). Significant differences in the number of fibrinogen binding sites per platelet between individual donors was observed (donor A, approximately 50,000 sites; donor B, approximately 20,000 sites), which confirms previous reports.^{14,24,25}

Both Fig 3 and Table 3 contain data derived from quantitative binding analyses performed under nonstirring conditions at 25°C . Two additional fibrinogen binding experiments were performed at 37°C under nonstirring conditions

Table 3. Quantitative Effect of AP3 and Tab on the Interaction of Fibrinogen With Platelets

Donor	Antibodies	Dissociation Constant ($\mu\text{mol}/\text{L}$)	Molecules Bound/Platelet
A	None	0.50 ± 0.14	$54,300 \pm 7,600$
A	AP3 + Tab	0.32 ± 0.06	$42,400 \pm 3,700$
B	None	0.54 ± 0.14	$19,800 \pm 2,650$
B	AP3 + Tab	0.33 ± 0.06	$17,400 \pm 1,300$

^{125}I -fibrinogen was added in increasing amounts to platelets ($1 \times 10^8/\text{mL}$) until saturation was reached. AP3 and Tab, when present, were at $20 \mu\text{g}/\text{mL}$ final concentration each. Binding data were analyzed using the weighted, nonlinear curve fitting program LIGAND. Values reported are the mean of three determinations $\pm$ SE using platelets from two different donors, A and B.

in test tubes. The results obtained at 37°C (not shown) were nearly identical to those shown in Fig 3 except that the total number of fibrinogen molecules bound to the platelet surface at saturation was in each case reduced by approximately 50%. This effect of temperature on fibrinogen binding has been previously documented in detail by Marguerie and Plow.²⁶ To ensure that fibrinogen binding to platelets in the presence of AP3 plus Tab also occurred at 37°C under stirring conditions, we performed three additional experiments in which we measured fibrinogen binding directly in an aggregometer with stirring at 1,000 rpm at 37°C . The results obtained in the aggregometer are comparable to those obtained in a test tube, though we did see a higher degree of nonspecific binding and trapping within platelet aggregates as was expected. As shown in Table 4, AP3 plus Tab did not inhibit the number of ^{125}I -fibrinogen molecules that become associated with platelets, whereas AP2 or EDTA both significantly reduced fibrinogen binding. Aggregation was completely blocked by EDTA, AP2, or AP3 plus Tab, as before. Thus, inhibition of aggregation by AP3 plus Tab seems to occur in the presence of apparently normal fibrinogen binding under all conditions tested (ie, 25°C and 37°C , stirring or nonstirring).

Effects of AP3 and Tab on thrombin-induced fibrinogen binding. To determine whether the effects of AP3 plus Tab on fibrinogen binding were limited to ADP-induced activation, we repeated the aforementioned studies using thrombin as the agonist. As discussed earlier, thrombin-induced platelet aggregation was completely inhibited by AP2 or AP3 plus Tab but not at all by AP3 or Tab alone, analogous to our observations using ADP as the agonist. Neither AP3 alone nor Tab alone inhibited the binding of fibrinogen to thrombin-stimulated platelets, also corresponding to our observations using ADP as the agonist. When platelets were preincubated with AP3 plus Tab, thrombin-induced fibrinogen binding was completely blocked, thereby mimicking the action of AP2 alone (Fig 4). When platelets were activated with thrombin/hirudin prior to rather than following incubation with AP3, Tab, and fibrinogen, fibrinogen binding was also blocked, which demonstrated that these antibodies block thrombin- but not ADP-induced fibrinogen binding when

Table 4. Semiquantitative Measurement of Fibrinogen-Platelet Association at 37°C Under Stirring Conditions

Antibody	Aggregation	Bound cpm	μg Fibrinogen Bound per 10^8 Platelets
None	+	8,000	1.3
$10 \text{ mmol}/\text{L}$ EDTA	—	5,400	0.89
AP2	—	5,424	0.89
AP3 + Tab	—	10,150	1.6

Washed platelets at $1 \times 10^8/\text{mL}$ in a volume of $400 \mu\text{L}$ were preincubated in an aggregometer under stirring conditions with $200 \mu\text{g}/\text{mL}$ radiolabeled fibrinogen and $20 \mu\text{g}/\text{mL}$ of each indicated monoclonal antibody for ten minutes at 37°C . Platelet activation was initiated by the addition of ADP up to $20 \mu\text{mol}/\text{L}$. After five minutes, $75 \mu\text{L}$ was withdrawn and centrifuged through $500 \mu\text{L}$ of 15% sucrose to separate bound from free ligand. Following aspiration of the supernatant, the radioactivity associated with the platelet pellet was determined in a gamma counter. Specific activity of the labeled fibrinogen was $81,000 \text{ cpm}/\mu\text{g}$.

Fig 4. Effect of AP3 and Tab on fibrinogen binding to thrombin-activated platelets. Binding conditions were identical to those described for the inset to Fig 3 except that 0.1 U/mL of α -thrombin was used as the agonist and all incubations were performed at 37 °C rather than 25 °C. -Plts, no platelets added, representing nonspecific binding to the incubation tube; -Agon, no ADP or thrombin added; +EDTA, platelets incubated with agonist but in the presence of 5 mmol/L EDTA; c, control tube containing platelets and agonist. Antibodies added where indicated were at final concentrations of 10 μ g/mL each. Note that AP3 plus Tab block thrombin- but not ADP-induced fibrinogen binding (ie, compare Fig 3 inset with this Fig). Platelet aggregation is inhibited by using either agonist.

bound to either the activated or inactivated platelet surface. These data are summarized in Fig 4, and the effects of these antibodies, alone and in combination, on selected platelet functions are summarized in Table 2.

Effect of AP3 and Tab Fab fragments on platelet function. The monoclonal antibodies used in all of the aforementioned experiments were in the form of intact IgG, which by analogy with other antireceptor antibodies have the ability to interact with two identical epitopes, thus raising the possibility of cross-linking nearby membrane receptors. To determine whether lateral cross-linking of adjoining GPIIb-IIIa complexes might play a role in the synergistic action of AP3 and Tab on inhibition of platelet aggregation, monovalent Fab fragments were prepared and used in studies comparable to those reported above. Fab fragments of both AP3 and Tab were found to have similar binding affinities for the platelet surface as their corresponding intact IgGs, as judged by their effectiveness in competing for radiolabeled intact IgGs. Like their intact counterparts, Fab fragments of AP3 alone or Tab alone had no effect on ADP- or thrombin-induced platelet aggregation or secretion. Unlike intact IgG, however, the combination of Fab fragments of both AP3 and Tab at concentrations of up to 50 μ g/mL each also was without effect on platelet function. Interestingly, the combinations of intact AP3 IgG together with Tab Fab fragments or intact Tab IgG together with AP3 Fab fragments also were unable to inhibit platelet aggregation or secretion induced by either ADP or thrombin. Thus, it appears that both antibodies must be divalent for them to exert their synergistic inhibitory effect on platelet aggregation and secretion. To test whether the use of Fab fragments was not merely removing a steric block that intact IgGs might place on fibrinogen binding, thereby allowing platelets to aggre-

gate, platelets were additionally incubated with 50 μ g/mL of affinity purified, fluorescein isothiocyanate-conjugated, goat antimouse IgG subsequent to saturating the platelet surface with Fab fragments of AP3 and Tab. Binding of the second antibody was verified by immunofluorescent microscopy and did not occur without prior incubation of platelets with murine antibodies. Under these conditions, ie, with both Fab fragments and intact IgGs on and near the platelet fibrinogen receptor, platelet aggregation and secretion still proceeded normally. Binding of goat antimouse IgG to intact AP3 and Tab on the platelet surface did not affect their ability to block platelet aggregation and secretion, thus ruling out any effect on platelet aggregation by the second antibody alone. These studies are summarized in Table 2.

DISCUSSION

There is now compelling evidence that membrane GPIIb and IIIa are the major components of the human platelet fibrinogen receptor. First, platelets from patients with type I Glanzmann's thrombasthenia, which contain less than 5% of the normal levels of GPIIb-IIIa, fail to bind detectable levels of fibrinogen following stimulation with ADP.^{5,13,14,25} Second, monoclonal antibodies raised against the GPIIb-IIIa complex mimic the thrombasthenic condition by inhibiting both fibrinogen binding and platelet aggregation.¹⁵⁻¹⁸ Third, UV irradiation of photoaffinity-labeled fibrinogen resulted in its incorporation into GPIIb.²⁷ Fourth, Nachman and Leung have demonstrated complex formation of purified GPIIb-IIIa with fibrinogen attached to plastic microtiter wells.²⁸ Gogstad et al²⁹ using crossed immunoelectrophoresis have shown that radiolabeled fibrinogen binds to immunoprecipitin arcs containing the intact GPIIb-IIIa complex but not to precipitin arcs given by the dissociated glycoproteins. Finally, purified GPIIb-IIIa complexes incorporated into phospholipid vesicles retain the ability to bind fibrinogen in a dose-dependent, saturable manner.^{30,31}

In this report, we have used three well-characterized monoclonal antibodies directed against the components of the platelet fibrinogen receptor to further investigate the molecular requirements for fibrinogen binding and platelet-platelet cohesion. Using a series of complimentary competitive inhibition experiments, we showed that AP2, AP3, and Tab did not compete with each other in binding to the GPIIb-IIIa complex of intact platelets. Moreover, the combination of AP3 and Tab did not inhibit the binding of AP2 to its GPIIb-IIIa complex-specific determinant. Taken together, it appears that three different monoclonal antibodies (150,000 daltons each) can occupy a single platelet fibrinogen receptor (molecular weight about 230,000) simultaneously.

Both ADP-induced platelet aggregation and secretion were unaffected by saturating levels of either AP3 or Tab. When these two antibodies were added together, however, both of these processes were completely inhibited, mimicking the effects of AP2 alone. In light of the fact that AP2 alone or AP3 plus Tab inhibited ADP-induced platelet aggregation, it was not surprising that secretion was also suppressed because ADP-induced release is known to occur subsequent to and be dependent upon the occurrence of primary aggre-

gation.^{24,32-34} Since ADP-induced fibrinogen binding and primary aggregation are also normal in aspirin-treated platelets,³⁵ which also are incapable of secretion, it is obvious that the failure of platelets to aggregate in the presence of AP3 plus Tab is due to something other than inhibition of the release reaction. Thrombin-activated platelets also did not aggregate in the presence of AP3 plus Tab or AP2 alone, though the release reaction, which unlike ADP activation occurs prior to aggregation, was unaffected. Thus, these data provide further evidence that induction of secretion alone is insufficient stimulus to initiate platelet aggregation.

It is noteworthy that AP3 and Tab exert their synergistic inhibitory effect on both ADP- and thrombin-induced platelet aggregation through two apparently distinct mechanisms. When ADP is used to activate platelets, fibrinogen binding is both quantitatively and qualitatively normal insofar as we have been able to measure (Table 3 and Fig 3), yet aggregation and release are totally blocked (Fig 2, Table 2). Thrombin-activated platelets, however, neither bind fibrinogen (Fig 4) nor aggregate in the presence of AP3 plus Tab, yet the release reaction is normal. That thrombin initiates surface membrane changes at or near the platelet fibrinogen receptor distinct from that generated by ADP activation is further supported by previous studies showing that (1) thrombin, but not ADP, is able to expose binding sites for fibronectin on the platelet IIb-IIIa complex³⁶; (2) thrombin, but not ADP, induces thrombospondin binding to platelets³⁷; and (3) ADP- but not thrombin-induced Ca^{+2} influx is inhibited by two different GPIIb-IIIa complex-specific monoclonal antibodies.³⁸ Although none of these experiments, including the ones presented in this manuscript, are completely understood at a molecular level, taken together they emphasize the complexity and multiple modes by which the platelet surface can become activated.

The observation that ADP-induced platelet aggregation is completely blocked in the presence of apparently normal fibrinogen binding deserves further comment. There are several plausible explanations why platelet cohesion might be inhibited although binding of fibrinogen to the platelet surface has occurred. We cannot totally exclude the possibility that fibrinogen binding is somehow qualitatively altered when Tab and AP3 occupy sites on GPIIb and GPIIIa, though several lines of evidence argue against this. If the binding of fibrinogen to the platelet surface was anomalous in the presence of AP3 plus Tab or if fibrinogen was interacting with either of the two antibodies, a change in either the number of fibrinogen molecules bound, the affinity of fibrinogen for the platelet surface, or both would be detected. Our data (Fig 3 and Table 3) demonstrate that neither of these two binding parameters were altered in the presence of one or both of these two monoclonal antibodies, indicating that other modes of inhibition must be considered.

Since Fab fragments of AP3 or Tab are unable to inhibit platelet aggregation even when only one of the two antibodies used is a Fab, these studies suggest that AP3 and Tab exert their synergistic inhibitory effect on ADP-induced platelet aggregation and secretion by a divalent antibody-dependent mechanism rather than by sterically modifying the way in which fibrinogen binds to the platelet surface. The failure of an intact second antibody bound to multiple sites of surface-bound Fab fragments of AP3 and Tab to reconstitute the inhibition of ADP-induced platelet aggregation further argues against simple steric hindrance as the mechanism by which AP3 Tab inhibits platelet aggregation.

Inasmuch as ADP-induced fibrinogen binding appears to be unaffected by AP3 plus Tab, it is likely that the lack of aggregation in the presence of these two antibodies represents the inhibition of a physiologically important event that occurs subsequent to fibrinogen binding to the platelet surface. In this regard, monoclonal antibodies directed against either thrombospondin³⁹ or fibronectin⁴⁰ have also been reported to inhibit platelet aggregation by unknown mechanisms. It is possible that fibrinogen-fibrinogen associations between adjacent platelets may play a role in platelet cohesion and antithrombospondin, antifibronectin, and AP3 plus Tab all block platelet aggregation by decreasing the affinity of fibrinogen-coated platelets for each other. On the other hand, by analogy with other cell surface receptors, eg, those for insulin or IgE, it is reasonable to speculate that reorganization and/or clustering of cell surface molecules might play a role in platelet activation. Employing diverse methodologies including immunoelectron microscopy,⁴¹⁻⁴⁴ chemical cross-linking,⁴⁵ and kinetic analyses of fibrinogen binding,³⁵ several investigators have found evidence for interaction of fibrinogen receptors following platelet activation. The combination of AP3 and Tab may somehow interfere with activation-induced association of fibrinogen receptors with each other or the underlying cytoskeleton. It is noteworthy that Estry and colleagues⁴⁶ have recently reported that fibrinogen binds normally to platelets of dogs with congenital thrombopathia, a hereditary disorder of platelet function characterized by a thrombasthenialike defect in aggregation but quantitatively normal levels of GPIIb-IIIa.^{47,48} The intriguing possibility exists that AP3 plus Tab are introducing a defect similar to that found in canine thrombopathia. Using immunoelectron microscopy in conjunction with other methods, we plan to address questions concerning the interaction and possible reorganization of fibrinogen receptors following platelet activation.

Characterization of Monoclonal IgG Cryoglobulins: Fine-Structural and Morphological Analysis

By D.N. Podell, C.H. Packman, J. Maniloff, and G.N. Abraham

The morphology of the amorphous, gelatinous, and crystalline varieties of monoclonal IgG cryoglobulins was analyzed by light and transmission and scanning electron microscopy. Each cryoglobulin had a characteristic fine structure that correlated with its gross morphology. Transmission electron microscopy showed that the amorphous precipitates were random and disorganized molecular clumps. In contrast, cryogels were thin-walled, well-organized, and hydrated strawlike clusters, whereas cryocrystals formed tightly compacted, highly structured molecular clusters.

MONOCLONAL HUMAN IgG cryoglobulins without defined antibody activity have unique immunologic and biochemical characteristics.¹⁻³ Their primary,⁴ secondary, and tertiary⁵⁻⁷ structural properties cause self-association and precipitation from chilled solutions by diverse biophysical processes.⁵⁻¹² The cryoglobulinemic syndrome resulting from these molecular interactions is caused by cryoglobulin polymerization or precipitation *in vivo*, which produces signs of complete or partial small-vessel occlusion with or without accompanying hyperviscosity. Due to differences in their structural and biophysical properties, IgG cryoglobulins may assume amorphous, gelatinous, and/or crystalline morphological forms *in vitro*, either in the patient's serum or in solution after purification.¹³

The severity of the cryoglobulin-related clinical disease is related to the morphology of the IgG cryoprecipitate and the nature of the *in vivo* aggregate or molecular complex that forms. Clinically, the vascular occlusion causes skin lesions that range from superficial purpura to deep gangrenous ulcers in dependent areas. In general, the most severe symptoms are associated with crystalline cryoprecipitates⁴ and the mildest with gelatinous cryoprecipitates.

Although the processes of cryogel and the cryocrystal self-association and subsequent precipitation differ,^{5-7,10} differences in the structure of the various types of cryoprecipitates have not been previously described. In this report, monoclonal IgG cryoglobulins with defined biophysical properties were purified from patient sera and studied by light and scanning and transmission electron microscopy to determine their ultrastructural properties. These findings may clarify, in part, how these proteins produce their diverse clinical symptomatology.

MATERIALS AND METHODS

DUB (IgG₁K), WEB (IgG₁), and LON (IgG₁) were purified from each patient's serum as previously described.^{3,13} Each formed a visibly different cryoprecipitate after incubation of the serum at 4 °C for seven days. IgGs DUB and WEB both produced flocculant white precipitates. After gentle manual inversion, the WEB cryoprecipitate appeared finely dispersed, and the solution showed a silky sheen characteristic of suspensions of microcrystals. The cryoprecipitate formed by IgG DUB was more flocculant, appeared in visible clumps (0.1 to 0.25 mm in size), and did not show the sheen noted for WEB. IgG LON formed a firm, opaque, cryogel that occupied the entire serum volume. The tube in which the LON cryogel formed was able to be completely inverted with minimal loss of serum.

Crystals that formed in blood produced rouleaux, and analysis by scanning electron microscopy indicated that the crystals could form thick-walled, branching, macromolecular nets that could physically trap cells. The morphological properties provided visual impressions by which cryoglobulins could cause clinical disease secondary to vascular occlusion produced by self-associated IgG cryoglobulin molecules.

© 1987 by Grune & Stratton, Inc.

The amorphous and crystalline cryoglobulins and a portion of cryogel LON were gently dispersed in ice-chilled phosphate-buffered saline (PBS) (0.01 mol/L phosphate buffer, 0.154 mol/L NaCl, pH 7.4) and collected by centrifugation at 200 rpm for 20 minutes at 4 °C. Each was then dissolved in PBS at 37 °C and reprecipitated by 24 to 48 hours of incubation at 4 °C. This process was repeated four times to rid the cryoglobulins of trace contaminants of albumin. IgG LON was additionally dialyzed against 0.015 mol/L phosphate, pH 7.4, at 37 °C and passed through a diethyl aminoethyl column (equilibrated with the same buffer) at 37 °C. All three proteins were judged immunologically pure by immunoelectrophoresis with antisera specific for the human heavy-chain classes and light-chain types and produced isoelectric focusing profiles with markedly restricted heterogeneity, typical of purified myeloma proteins.³ In addition, isolated heavy and light chains yielded single aminoterminal primary amino acid sequences upon automated Edman degradation.³

For electron microscopy, purified cryoglobulins were allowed to reform at 4 °C in PBS, gently resuspended and added dropwise to ice-chilled 0.1% glutaraldehyde in 0.15 mol/L phosphate buffer, pH 7.4. The cryoglobulins were allowed to settle for 20 minutes and then collected by centrifugation at 200 rpm at 4 °C. Fixed cryoproteins were washed several times after resuspension in chilled 0.15 mol/L phosphate buffer (pH 7.4), postfixed in osmium tetroxide, alcohol dehydrated, and embedded in epoxy resin.

For transmission electron microscopy, 50 nm sections were stained with uranyl acetate prior to examination. The technique is similar to that described by Stoeber et al¹⁴ except that a lower concentration of glutaraldehyde was used.

Image analysis of micrographs was done using a 6-m optical bench with a 5-mW He-Ne laser as described previously.¹⁵

RESULTS

Light microscopy studies. Citrated blood samples from patients DUB, WEB, and LON were incubated at 4 °C for one hour. The tubes were mixed by gentle inversion to resuspend settled cells, and one drop from each sample was placed on a microscope slide. A cell monolayer was produced by spreading, and the cells were then stained with Wright's stain and examined. Samples from patients DUB and LON were unremarkable. However, that of WEB contained numerous rouleaux. As shown in Fig 1A, the erythrocyte clusters have crystals at their core. Figure 1B shows fusiform crystals of WEB, which formed in serum after ten minutes incubation at 4 °C and are morphologically similar to those noted in the centers of the rouleaux.

The following experiments demonstrated that rouleau formation was not due to agglutination of erythrocytes secondary to an antierythrocyte specificity for IgG WEB: (1) Noncryoprecipitating F(ab')₂ fragments prepared by pepsin digestion of IgG WEB did not hemagglutinate, whereas anti-Rh antibody did hemagglutinate washed WEB red cells in a microtiter hemagglutination assay.¹⁶ (2) Incubation of washed WEB red cells with ¹²⁵I-labeled F(ab')₂ of IgG WEB showed no greater uptake of label than did ¹²⁵I-labeled F(ab')₂ prepared from pooled normal human IgG that had been absorbed with both pooled human erythrocytes prior to pepsin digestion and IgG WEB bound to bromoacetyl cellulose.¹⁷ The background binding amounted to less than 1% of the total radioactivity added to the assay mixture.

Transmission electron microscopy. The cryoprecipitates were examined by transmission electron microscopy. Figure 2A shows the amorphous nature of IgG DUB.

Although the DUB cryoprecipitate has no obvious gross structure or molecular regularity, close examination reveals rare structures with the dimensions and shape of individual IgG molecules. Prolonged cultivation of the cryoprecipitate for up to 1 month in solutions of increasing salt concentrations (0.01 to 0.5 mol/L NaCl) did not change the amorphous nature of IgG DUB.

The cryogel IgG LON is shown in Fig 2B, C, and D. After purification, the LON cryoprecipitate formed narrow fibrils. Longitudinal cross sections of these fibrils (Fig 2C) show thin-walled, hollow tubules. In all sections studied, the tubules are organized into bundles that were seen in both horizontal (Fig 2B) and oblique (Fig 2D) cross-sectional cuts. The lack of density suggests a diffuse molecular structure containing a large amount of trapped water. Using polarized light, unfixed preparations of IgG LON were not refractive, in agreement with the lack of molecular order. No definite molecular organization or structure was noted in high-magnification photomicrographs.

In contrast, washed and purified WEB cryoprecipitates spontaneously formed microcrystals that were birefringent with plane polarized light. Bright-field light microscopy showed these microcrystals to be elongated and strawlike, either single or in bundles, from 20 to 400 or 500 μm in length.¹³ High-power electron micrographs of perpendicular, parallel, or oblique cuts to the long axis of the WEB crystals showed variations of the dense herringboned, cross-hatched pattern noted in the longitudinal sections shown in Fig 3. This pattern results from the self-association of IgG WEB molecules into highly organized and tightly packed crystals. Close examination shows individual IgG molecules with a

typical "Y" configuration. Optical diffraction analyses of 15,000 $\times$ electron micrograph negatives showed the units (IgG molecules) in the microcrystals to be in a helical arrangement with a periodicity of six to eight molecules and longitudinal and transverse dimensions of 140 $\text{\AA}$ and 100 $\text{\AA}$, respectively. The latter measurement represents the computed distance between the amino terminal ends of the two limbs of the f(ab) regions of an IgG molecule.

Scanning electron microscopy. Scanning electron microscopy of crystals of IgG WEB showed dense walls of the WEB crystals whose tips are sometimes irregular, fractured, and jagged (Fig 4D) and other times blunt and thick with rounded and curled over edges (Fig 4A). This side-to-side association produces the sheets of tubules shown in Fig 4A. The ability of the WEB crystals to branch and form smaller projections that stem from larger crystal trunks is seen in Fig 4B. The branching and intercollation can result in the netlike tangled array of crystals shown in Fig 4C.

To determine whether WEB crystals had the ability to trap blood cells, 10^7 washed WEB peripheral red and white blood cells in PBS, pH 7.4, were added to 1 mL of a warmed (37 $^{\circ}\text{C}$) solution of purified WEB cryocrystals (concentration, 1.5 mg/mL). The mixture was incubated at 4 $^{\circ}\text{C}$ for 24 hours. The cryocrystals and cells then were allowed to settle and the cell-crystal sediment prepared for electron microscopy. Figure 5 shows a photomicrograph of a single red cell enveloped by the WEB cryocrystal filaments. The photomicrograph demonstrates that cryocrystals sometimes can form around, physically trap, and immobilize cells in the interstices of the cryoprotein net.

DISCUSSION

The present studies demonstrate that the three morphological types of monoclonal IgG cryoglobulins form precipitates that have different fine ultrastructural characteristics. As shown by electron microscopy, cryoglobulins may self-

Fig 3. Transmission electron micrograph of a longitudinal section of cryocrystal IgG WEB. The dense herringbone pattern is produced by highly organized and tightly packed IgG molecules. Bar, 0.13 μm .

associate in many ways: (1) as amorphous cryoprecipitates without any discernible molecular organization; (2) as cryogels comprised of loosely organized tubular structures that appear highly hydrated; and (3) as cryocrystals that are dense, compact, highly organized structures with a periodic molecular array.

These studies also reveal another characteristic of IgG cryogel and cryocrystal globulins, namely, that they may amplify their size by organization of the basic tubular gel or crystalline units into large bundles. The size and complexity of the cryoprecipitate is enhanced by the ability of both the cryogel and cryocrystals to bend and also to form structural branch points from the larger cryoprotein trunks of the precipitate. For the cryocrystal this process produces a complex and dense cryoprotein network that may be associated with cellular aggregation. This is visually noted by the

Fig 4. Scanning electron micrographs of IgG WEB crystals. The micrographs demonstrate the ability of the crystals to branch and form nets and their thick tubular structure. Bar A, 1 μm ; B, 1.5 μm ; C, 4 μm ; D, 0.5 μm .

presence of the erythrocyte rouleaux in peripheral blood that contain a single cryocrystal at their central core. The cryoglobulin net may also physically trap cells. The scanning electron micrographs of IgG WEB show that purified WEB crystals can form tentaclelike, branched crystalline projections that may, upon crystallization, envelop and ensnare blood cells.

The clinical symptoms that accompany primary idiopathic IgG cryoglobulinemia are of variable severity. The symptoms are most likely due to the presence of self-associated IgG aggregates in the peripheral vasculature.^{1,4,18} In its most severe form, a necrotizing vasculitis manifested clinically by generalized skin ulcers is noted, which may become gangrenous. This is secondary to the occlusion of small blood vessels with cryoprecipitate and accompanied by a marked perivascular and intramural arteriolar inflammatory reaction.¹³ This situation should be contrasted with tissue or organ fixation and the renal and skin lesions that are associated with the more common mixed IgM-IgG cryoglobulins. These are true antigen-antibody complexes¹⁹ and in most instances avidly fix complement.¹⁸

The morphologies for IgG WEB and IgG LON correlate with their differing biophysical properties and their contrasting mechanisms for self-association. IgG LON forms thin-walled tubules after a four- to seven-day period of cryogelation. Biophysical studies^{6,7} demonstrate that these axially asymmetric IgGs form large polymers through weak non-ionic and hydrophobic self-associative interactions. Cryocrystals such as WEB aggregate with rapid concentration-dependent kinetics^{5,10} after the formation of a nucleation core that produces a dense molecular pack. Although primary amino acid sequence analyses demonstrate diverse primary structural mutations in both heavy and light chains of these proteins,⁴ their relationship to the cryoprecipitation process has not as yet been determined.

In sum, these morphological analyses provide a visual indication of how IgG cryoglobulin molecular self-associations may produce the small-vessel vascular insufficiency and blockade characteristic of idiopathic monoclonal IgG cryoglobulinemia. In addition, the analyses show the close correlation between fine structural morphology and gross characteristics of the three cryoprotein types.

Control of Hemopoiesis by a Bone Marrow Stromal Cell Clone: Lipopolysaccharide- and Interleukin-1-Inducible Production of Colony-Stimulating Factors

By D. Rennick, G. Yang, L. Gemmell, and F. Lee

A stromal cell line, GY30, was cloned from mouse bone marrow adherent cell layers. In culture, GY30 cells sustain the production of granulocyte-macrophage progenitor cells (GM-CFU) but fail to support the survival of pluripotential stem cells (CFU-S). GY30 cells secrete two growth factor activities distinct from interleukin-3 (IL-3), IL-2, and macrophage colony-stimulating factor (M-CSF) but functionally similar to GM-CSF and G-CSF. The production of both CSFs

is increased 70- to 200-fold by treating GY30 cells with lipopolysaccharide or IL-1. RNA blot analysis reveals the presence of GM-CSF and G-CSF transcripts and demonstrates that IL-1 regulates the production of both factors at the mRNA level. Further, these studies show that the GM-CSF secreted by GY30 cells is structurally similar to the GM-CSF produced by activated T cells.

© 1987 by Grune & Stratton, Inc.

IT HAS BEEN RECOGNIZED for some time that bone marrow is the major hemopoietic tissue in the adult animal. This tissue is the main source of multipotential stem cells as well as mature myeloid cells that are needed daily to replace short-lived circulating blood cells.¹ The development of clonal semisolid culture assays² has provided valuable information about the growth and differentiation of hemopoietic progenitor cells in response to colony-stimulating factors (CSFs) produced by various tissues and cell lines.³ These studies have led to the identification of several types of CSFs and the purification of four mouse factors termed interleukin-3 (IL-3) or multi-CSF,^{4,5} granulocyte-CSF (G-CSF),⁶ macrophage-CSF (M-CSF),⁷⁻⁹ and granulocyte-macrophage-CSF (GM-CSF).¹⁰ However, until recently, little was known about the specific mechanisms regulating hemopoiesis within the bone marrow. Following the development of techniques for growing bone marrow cells in liquid culture,¹¹ a series of studies showed that long-term maintenance of stem cell growth and differentiation in vitro is dependent on bone marrow-derived adherent cells.^{12,13}

The adherent cell layers consist of a heterogeneous mixture of macrophages, endothelial cells, fibroblasts, and adipocytes.¹⁴⁻¹⁷ These various cell types are collectively referred to as stromal cells. Initially, there was difficulty in demonstrating the presence of soluble CSFs in these long-term bone marrow culture systems, which led to the suggestion that stromal cells may regulate hemopoiesis primarily through cell-cell interactions.¹¹ Later it was shown that low levels of CSFs are produced by stromal cell layers¹⁸⁻²³ and that they could account in part for the growth and differentiation of granulocyte and macrophage progenitor cells in Dexter-type

cultures. However, the various types of CSF produced by stromal cells and their relationship to CSFs produced by other tissues have not been clearly established. Some cells within the stromal layer also modify the response of hemopoietic stem cells by producing colony-enhancing factors²⁴ or inhibitors of differentiation-inducing factors.²⁵⁻²⁹ Thus, adherent layers can provide in vitro both stimulatory and inhibitory signals that maintain the development of pluripotential stem cells while sustaining steady-state production of differentiated progeny in a manner similar to intact bone marrow.

Recent studies have used clonal stromal cell lines to identify specific mechanisms by which stromal cells regulate stem cell growth and differentiation. Li and Johnson³⁰ have described an adherent cell clone that supports colony formation by multipotential progenitor cells. The colony-stimulating activity associated with the stromal cell line is apparently not CSF-1 (M-CSF), GM-CSF, or IL-3 (multi-CSF). It has also been reported that a preadipocyte cell line in direct contact with hemopoietic cells sustains the proliferation of hemopoietic stem cells (CFU-S).³¹ Other cloned stromal cell lines have been shown to support colony formation by hemopoietic cells specifically committed to granulocyte-macrophage lineages,³²⁻³⁷ whereas another supports erythrocyte development as well.³⁸ Some of these lines have been shown to secrete M-CSF, which suggests a role for this factor in bone marrow-dependent hemopoiesis.^{20,33} It is apparent that these cell lines are morphologically and functionally diverse; thus they may represent some of the different cell types that constitute the hemopoietic inductive microenvironment.

Our studies with the bone marrow stromal cell clone GY30 examined the production of humoral factors and their relationship to CSFs derived from other sources. These results show that GY30 cells are functionally distinct from previously described stromal cell lines. In addition, we have investigated the possibility that CSF production by GY30 cells is regulated by various stimulants similar to the induction of CSF synthesis by T cells.

MATERIALS AND METHODS

Animals. CBA/J and C3H/HEJ mice (Jackson Laboratories, Bar Harbor, ME), aged 8 to 12 weeks, were used as a source of bone marrow cells.

Establishment of adherent cell layers. Bone marrow cells obtained by flushing the femurs of CBA/J and C3H/HEJ mice were plated at 1×10^6 cells/mL in modified Iscove's medium, 5×10^{-5} mol/L 2-mercaptoethanol (2-ME) and 10% fetal calf serum (FCS). Cultures established at 37 °C in a humidified atmosphere with 5% CO₂ in air were fed weekly by removing half of the medium and replacing it with fresh medium. After 3 months of continuous culture, adherent cells were trypsinized, washed, and one fifth of the cells were subcultured in new flasks. Cultures usually reformed an adherent layer after 2 weeks, at which time they were repeatedly passaged into new flasks.

Single-cell cloning. A dilute suspension of adherent layer cells was plated in a 100-mm Petri dish. With the aid of an inverted microscope, single cells were micropipetted and transferred to separate wells in a Falcon microtiter tray (Falcon Labware, Oxnard, CA) containing modified Iscove's medium, 2-ME, and 10% FCS. All wells were inspected for growth and clonality of the resulting line. Two clonal lines obtained by this method were used in this study. They are referred to as GY30 and HEJ.2 (derived from CBA/J and C3H/HEJ bone marrow cultures, respectively).

Histochemical and immunofluorescent staining. GY30 cells were removed from culture with a rubber policeman and applied to glass slides using a cytocentrifuge. The mounted cell preparations were stained for myeloperoxidase, chloroacetate esterase, alpha-naphthyl acetate esterase, alkaline phosphatase, and acid phosphatase by established histochemical methods.

GY30 cells were grown in a subconfluent layer in tissue culture chamber slides (Lab-Tek, Miles Scientific, Naperville, IL) for immunofluorescent staining of cell surface determinants. Growth medium was removed, and the adherent cells were overlaid with either anti-Ia^k, anti-H-2K^k, anti-Thy1.2, anti-Ly1, anti-Ly2 (Becton Dickinson, Oxnard, CA), or anti-Mac1 antibodies (gift of Robert Coffman, DNAX). Unrelated antibodies of the same isotypes as the specific monoclonals just mentioned were added to duplicate cultures to control for nonspecific binding. After 15 minutes, the slides were washed and fluorescein isothiocyanate (FITC)-conjugated rat antimouse IgG antibodies (Pel-Freez Laboratories, Rogers, AR) or FITC-conjugated rabbit antirat Ig antibodies (Robert Coffman) were added to the appropriate sample. After 30 minutes, the slides were washed, coverslipped, and examined with a Zeiss fluorescence microscope.

Preparation of conditioned medium. Fresh unsupplemented medium or medium containing various concentrations of phytohemagglutinin (PHA) (Wellcome Diagnostics, Buckenham, England), concanavalin A (Con-A) (Sigma Chemical Co, St Louis), lipopolysaccharide (LPS) (Sigma), phorbol 12-myristate 13-acetate (PMA) (Sigma), P388D1 macrophage supernatant, or recombinant IL-1 were added to confluent layers of GY30 or HEJ.2 cells. At various intervals (12 hours, 24 hours, and four days), the conditioned medium (CM) was collected, filtered through a 0.45-μm millipore membrane, and stored at -20 °C.

To prepare P388D1 CD, P388D1 macrophage cells were grown to a confluent layer in RPMI 1640, 10% FCS, and 5×10^{-5} mol/L 2-ME. The adherent layer was then cultured in fresh medium containing 0.5% FCS. After four days, the supernatant was harvested and stored as described.

Source of factors. Purified G-CSF (4×10^4 U/mL) was a gift of N. Nicola (Walter and Eliza Hall Institute). Purified M-CSF (CSF-1) at 2×10^4 U/mL was a gift of R. Shaduck (University of Pittsburgh School of Medicine). Purified recombinant IL-1 (10^6 U/mL) was a gift of P. Lomedico (Hoffman-La Roche, Nutley, NJ). Recombinant IL-2, IL-3, and GM-CSF were obtained from Cos 7 cells transfected with the corresponding cDNA clones as previously described.³⁹⁻⁴¹ One unit of IL-2, IL-3, G-CSF, M-CSF, or GM-CSF is defined as that amount of factor that stimulates

half-maximal [³H]-thymidine incorporation of factor-dependent lines cultured at 5×10^4 cells/mL.

Factor-dependent cell lines. MC/9 mast cells⁴² were grown in RPMI 1640, 5×10^{-5} mol/L 2-ME, and 10% FCS supplemented with recombinant IL-3. NFS-60 and DA 3 myeloid cell lines (both provided by J. Ihle, Frederick Cancer Research Institute) were subcloned by micromanipulation. A GM-CSF-responsive subclone of DA 3 cells, referred to as DA 3.15, was isolated and has been continuously grown for 6 months in basic medium supplemented with recombinant GM-CSF. A subclone derived from NFS-60 cells, referred to as NFS-60.4, has been maintained in basic medium and recombinant IL-3. The T cell line HT2 (supplied by S. Strober, Stanford University) was cultured in complete medium containing recombinant IL-2.

Proliferation assays. Factor-dependent cells were cultured at 5×10^3 cells/well (Falcon microtiter trays) in RPMI 1640, 4% FCS, 5×10^{-5} mol/L 2-ME, and varied concentrations of test supernatants. During the last six hours of a 24-hour incubation period, each culture was pulsed with 0.5 μCi [³H]-thymidine. The cells were harvested onto glass fiber filters, and the radioactivity was measured in a liquid scintillation spectrometer.

Spleen colony-forming unit assay. The CFU-S content of cultured or fresh bone marrow cells was assayed by the method of Till and McCulloch.⁴³ Each lethally irradiated (900 rad) CBA/J mouse was injected intravenously with one fifth of the nonadherent bone marrow cells harvested from a single culture flask that had been seeded with 5×10^5 nonadherent bone marrow cells. Control groups were injected with 10^5 fresh bone marrow cells or received no cells. After ten days, the spleens (five mice per group) were removed and fixed in Bouin's solution and the splenic nodules counted using a dissecting microscope. The average background spleen colony count in mice not injected with cells was <0.5 per spleen. The average count in the control group receiving 10^5 uncultured bone marrow cells was 17 ± 4 .

Bone marrow colony-forming assay. Bone marrow cells were suspended at 1×10^6 cells/mL in RPMI 1640 with 2% FCS and incubated in tissue culture-grade Petri dishes for two hours. The nonadherent cells were harvested and cultured at 10^5 cells/mL in 35-mm Petri dishes containing modified Iscove's medium, 25% FCS, 5×10^{-5} mol/L 2-ME, 0.8% (wt/vol) methylcellulose using either IL-3, GM-CSF, or GY30 CM as a source of growth factor. After three days of culture, 1 U/mL erythropoietin (Step III, Terry Fox Laboratories, Vancouver, BC, Canada) was added to one set of duplicate cultures. Colonies consisting of more than 50 cells were counted on day 7. Individual colonies were applied to glass slides and stained with Wright-Giemsa for morphological analysis.

Endotoxin determination. Purified recombinant IL-1 was assayed for the presence of endotoxin using the limulus amoebocyte lysate test (E-toxate kit, Sigma). IL-1 prepared at 10, 1, and 0.1 U/mL was compared with various concentrations of an *Escherichia coli* endotoxin reference (Lot EC-1) according to the E-toxate procedure. The limit of detection of endotoxin is 0.05 to 0.2 ng/mL.

Preparation of mRNA and RNA blot analysis. GY30 cells were harvested from flasks by treatment with trypsin and then lysed with guanidine thiocyanate according to the procedure of Chirgwin et al.⁴⁴ The total cellular RNA was isolated by centrifugation through CsCl and recovered by ethanol precipitation. PolyA⁺ RNA was isolated following oligo (dT) cellulose chromatography.⁴⁵ As a control, mRNA was also isolated from the helper T cell clone Cl.Ly1+2-/-⁴²

For RNA blot analysis, polyA⁺ RNA was denatured and treated with formaldehyde as described by Maniatis et al.⁴⁶ and then fractionated on a 1% agarose gel containing formaldehyde. The RNA was then transferred to a nylon/nitrocellulose filter (Nytran, Schleicher and Schuell, Keene, NH). Filters were prehybridized and

hybridized in $6\times$ SSPE containing 50% formamide⁴⁷ at 55 °C. The GM-CSF probe was made using a *Bam*HI fragment containing a full-length mouse GM-CSF cDNA⁴⁰ subcloned into the GEM-1 vector (Promega Biotec, Madison, WI) that carries the SP6 promoter. ³²P-labeled RNA probe was synthesized in vitro using SP6 RNA polymerase and ³²P-cytidine triphosphate or ³²P-guanosine triphosphate essentially as described by Melton et al.⁴⁸ The G-CSF probe was made by fill-in labeling of synthetic oligonucleotides corresponding to residues 68 to 163 and 599 to 694 of the mouse G-CSF cDNA clone.⁴⁹ Following overnight hybridization, RNA blots were washed in $0.1\times$ SSPE at 65 °C and then exposed to x-ray film.

Biosynthetic labeling and analysis of extracellular matrix proteins. Cell lines were labeled with 50 μ Ci/mL of [³H]-proline (100 Ci/mmol; Amersham Corp, Arlington Heights, IL) in 5 mL of RPMI medium supplemented with 100 μ g/mL ascorbate, 64 μ g/mL 2-amino-propionitrile fumarate, and 5% dialyzed FCS. Cells were labeled for 24 hours, and the medium was harvested. The following were then added to the medium: EDTA (20 mmol/L), N-ethyl maleimide (10 mmol/L), and phenylmethyl sulfonylfluoride (1 mmol/L). The proteins were precipitated by the addition of solid ammonium sulfate to a 45% saturation followed by stirring overnight at 4 °C. The precipitated protein was collected by centrifugation, then the pellet was resuspended in and dialyzed extensively against 0.03 mol/L Tris-HCl, pH 7.8, 2 mol/L urea, 0.1% Triton X-100, and 0.02 mol/L EDTA. Aliquots of the labeled proteins were then treated with pepsin or collagenase essentially as described by Zipori et al.⁵⁰ and analyzed under reducing conditions by sodium dodecyl sulfate-polyacrylamide gel electrophoresis in 5% gels.⁴⁷ [³H]-labeled type I and type IV collagen standards were kindly provided by Dr B. Blumberg (University of California, Los Angeles).

Assay of angiotensin-converting enzyme activity. Angiotensin-converting enzyme activity was assayed by a spectrophotometric method using the ACE kit purchased from Sigma. GY30 cell lysate from 10^6 cells was prepared by adding 3 mL of 0.05 mol/L HEPES buffer, pH 8.0, containing 0.15 mol/L NaCl and 1% vol/vol Triton X-100. After 30 minutes the cells were removed from the flask with a rubber policeman and homogenized. Aliquots of GY30 homogenate and angiotensin-converting enzyme standard were assayed for activity according to the ACE kit procedure.

Electron microscopy. GY30 cells were fixed with 2.5% glutaraldehyde in 0.1 mol/L cacodylate buffer, pH 7.4, containing 0.05% CaCl₂. The fixative was replaced with 0.1 mol/L cacodylate buffer with 0.05% CaCl₂ and 7% wt/vol sucrose. Cells were postfixated with 1% OsO₄, dehydrated in an ascending ethanol series, and then embedded in Epon. Thin sections were stained with uranyl acetate and lead citrate and examined and photographed with a Philips EM 201 electron microscope.

RESULTS

Derivation and morphological characterization of cloned stromal cell lines. An adherent layer of CBA/J bone marrow cells was established in long-term culture for 3 months with weekly feeding. During this period a steady production of nonadherent hemopoietic cells was sustained. Morphological examination of the nonadherent population revealed maturing neutrophilic granulocytes and macrophages. After the initial 3-month culture period, nonadherent cells were discarded, and the adherent cells were passaged every other week. One of the subcultures was able to quickly reform a confluent layer of cells and could be readily cloned by micromanipulation. Twenty-two clones were suc-

cessfully derived from 182 micropipetted cells. Neither the adherent layers nor the resulting cloned lines require exogenous factors for growth, except those contained in FCS.

One clone, designated GY30, survived more than 20 passages and was selected for further study. Although GY30 cells do not display density-dependent growth typical of primary cell cultures, they cease growing in vitro after reaching confluency and do not form tumors when injected into normal or sublethally irradiated (400 rad) CBA/J mice. In vitro, this clone grows with an approximate doubling time of 30 to 48 hours and consists of large flat cells (Fig 1A) that form a confluent monolayer with a cobblestone appearance. If cultures are allowed to become confluent for 8 weeks or longer, approximately 3% of the cells spontaneously accumulate lipid vacuoles (Fig 1B). Lipid accumulation has been observed in preadipocytes that may be of fibroblastoid or epithelial cell origin. Although the significance of adipogenesis is not clear, it seems to be related to growth arrest.⁵¹ We have also found that GY30 cells are myeloperoxidase-, acid phosphatase- and nonspecific esterase-negative but chloroacetate esterase- and alkaline phosphatase-positive. Further, they have the following surface phenotype: H-2+, Thyl+,

Fig 1. Phase-contrast micrographs of GY30 adherent cells. (A) Actively growing cultures. (Original magnification $\times 300$; current magnification, $\times 96$. (B) Eight-week-old stationary cultures wherein approximately 3% of GY30 cells have undergone adipogenesis. (Original magnification $\times 300$; current magnification $\times 102$.)

Ia⁺, Lyl⁺2⁺, Mac1⁺. These results indicate that GY30 cells are not macrophages.

Analysis of extracellular matrix proteins biosynthetically labeled with [³H]-proline revealed that GY30 cells synthesize predominantly type I collagen along with small amounts of collagen types IV and V (Fig 2). This profile of collagen production suggests that GY30 cells share properties with both fibroblasts and endothelial cells.⁵² Electron micrographs of GY30 cells failed to demonstrate Weibel-Palade bodies, which have been identified as specific components of arterial endothelial cells *in situ*.⁵³ Further, the endothelial origin of GY30 cells could not be established by the presence of angiotensin-converting enzyme activity.^{54,55} Thus, GY30 cells are tentatively classified as fibroendotheliallike cells.

Using the same methodology, several stromal cell lines were cloned from an established adherent layer of C3H/HEJ bone marrow cells. The line referred to as HEJ.2 had properties similar to GY30 cells, and its use in certain experiments will be described later.

Effects of GY30 adherent layer and GY30 CM on CFU-C

Fig 2. Analysis of [³H]-proline-labeled extracellular proteins. GY30 cells were incubated with [³H]-proline as described in Materials and Methods. Proteins in the medium were concentrated by ammonium sulfate precipitation and then analyzed by polyacrylamide gel electrophoresis following treatment with pepsin or collagenase. The position of collagen standards is indicated. The gel was fixed and then soaked in a fluorographic solution (Enlightning, New England Nuclear, Boston) prior to autoradiography.

and CFU-S production. Adherent cell-depleted bone marrow cells (5×10^5) were seeded on top of a confluent layer of GY30 cells or cultured in 30% GY30 CM. At weekly intervals, two identical cultures from each set were terminated, and all of the nonadherent cells were harvested by gently washing the bottom of the flask. The total cell production and CFU-C and CFU-S content were determined at each time point. The number of CFU-C and CFU-S present in the uncultured nonadherent bone marrow cells was assayed as described in Materials and Methods. It was calculated that 5×10^5 fresh bone marrow cells contained 85 CFU-S and 1.15×10^3 CFU-C when cultured in IL-3.

The total number of viable cells recovered from cultures supplemented with GY30 CM rapidly declined after the second week of culture, whereas a steady production of mature neutrophilic granulocytes and macrophages was maintained in cultures containing GY30 adherent layers (Fig 3A). Moreover, cells recovered from cultures supplemented with GY30 CM failed to form hemopoietic colonies when plated in semisolid culture medium with IL-3 and erythropoietin (Fig 3B). However, a small but significant number of colony-forming cells (CFU-C) were detected for many weeks in cultures where hemopoietic cells were in direct contact with the GY30 cell layer. The colonies

Fig 3. Hemopoietic cells recovered from long-term cultures containing GY30 adherent cells or GY30 CM. (A) Results are expressed as the mean number of nonadherent cells harvested from duplicate cultures containing GY30 adherent layers (●—●) or only GY30 CM (○—○). Each culture flask contained 5×10^5 nonadherent cells in a total volume of 5 mL. The adherent layer cultures were fed biweekly by removing half of the medium and replacing it with fresh unsupplemented medium, and the other set of cultures were replenished with GY30 CM at 48-hour intervals. Any cells removed during the exchange of medium were added back to the respective cultures. Control cultures contained 5×10^5 nonadherent cells plated in the absence of an adherent layer or CM. After 1 week of incubation, there were no viable cells detected in these control cultures. (B) Results are expressed as the mean number of colony-forming cells (GM-CFU) recovered from duplicate cultures harvested at each time point; GY30 adherent layers (●—●), GY30 CM (○—○), and unsupplemented medium (△—△). To enumerate GM-CFU, nonadherent cells from each culture were divided between three 35-mm dishes containing semisolid growth medium supplemented with 1,000 U/mL of IL-3 and 1 U/mL of erythropoietin as described in the text. The resulting colonies consisting of greater than 50 cells were scored after seven days of incubation.

detected in the CFU-C assay consisted entirely of neutrophilic granulocytes and macrophages.

At the same time points, cells harvested from identical parallel cultures were tested for CFU-S content. We found that they failed to form spleen colonies when injected into lethally irradiated mice (data not shown). These results suggest that GY30 cells fail to support pluripotential (CFU-S) whereas they are capable of maintaining a fraction of the granulocyte-macrophage progenitor cells (GM-CFU) present in the original input nonadherent bone marrow population. Alternatively, GY30 cells may support a small number of pluripotential cells that are undetectable by the CFU-S assay, but these stem cells give rise to a modest number of GM-CFU during long-term culture. Our data do not discern between these possibilities.

Production of colony-stimulating activity. The colony-stimulating activity of GY30 CM collected four days after the last medium change was evaluated in conventional semisolid bone marrow cultures. The results presented in Table 1 show that GY30 CM stimulates a significant number of nonerythroid colonies compared with IL-3 and GM-CSF. Despite the presence of erythropoietin, no pure or mixed erythroid colonies above background levels were observed. When the cellular composition of individual colonies was examined, they were found to consist entirely of neutrophilic granulocytes, macrophages, or a mixture of the two cell types.

Characterization of the colony-stimulating activities using factor-dependent cell lines and cDNA probes. To further characterize the colony-stimulating activities pro-

duced by GY30, supernatant was collected four days after the addition of fresh medium and was examined in 24-hour proliferation assays using factor-dependent cell lines. The cell lines selected for this study have been characterized with respect to their dependence on several defined growth factors (Fig 4A to D). Purified macrophage colony-stimulating factor (M-CSF) does not stimulate any of these cell lines. Only HT2 T cells responded to recombinant IL-2. The mast cell line MC/9 and the myeloid cell lines NFS 60.4 and DA 3.15 are all stimulated to proliferate by recombinant IL-3. However, NFS 60.4 and DA 3.15 cells are also stimulated by purified G-CSF and recombinant GM-CSF, respectively. Thus, the pattern of response of this cell panel was used to functionally identify as well as quantitate growth factor activities present in test supernatants.

We found that GY30 CM (day 4) fails to stimulate proliferation of IL-2-dependent HT2 T cells (Fig 4A) and IL-3-dependent MC/9 mast cells (Fig 4B). However, it does support proliferation of NFS 60.4 cells (Fig 4C) and DA 3.15 cells (Fig 4D). Taken together, these data show that GY30 stromal cells produce colony-stimulating activities distinct from IL-2, IL-3, and M-CSF but functionally similar to GM-CSF and G-CSF.

These data do not rule out the possibility that GY30 cells also produce M-CSF. However, the low frequency of macro-

Table 1. Colony-Stimulating Activity of GY30 CM

Nonadherent bone marrow (BM) cells were suspended at 10^5 cells in 1 mL of methylcellulose culture medium supplemented with various concentrations of GY30 CM. Control cultures contained IL-3 or GM-CSF as a source of growth factor. After three days of incubation, 1 unit of erythropoietin (EPO) was added. On the seventh day, the resulting colonies consisting of 50 or more cells were counted.

*Data from triplicate cultures are expressed as means $\pm$ SEM.

†All of the colonies from two cultures were picked, applied to glass slides, and analyzed after staining fixed cells with Wright-Giemsa. The cellular composition of individual colonies was as follows: 58% granulocyte, 7% macrophage, and 35% mixed granulocyte/macrophage.

Fig 4. [^{3} H]-thymidine incorporation of factor-dependent cell lines stimulated by defined growth factors and GY30 CM. A quantity of 5×10^3 factor-dependent cells per culture (0.1 mL total volume) were incubated for 24 hours in growth medium supplemented with varying concentrations of IL-3 (■—■), IL-2 (▲—▲), GM-CSF (○—○), G-CSF (●—●), M-CSF (△—△), or day 4 GY30 CM (□—□). Each culture was pulsed with [^{3} H]-thymidine during the last six hours of incubation and harvested onto glass fiber filters and the radioactivity determined. Titrations of GY30 CM and various stock solutions of defined growth factors (adjusted to approximately 1,000 U/mL) were started at 1:2 dilutions in the first well. Results of triplicate cultures are expressed as the mean counts per minute $\pm$ SEM. (A), HT2 T cells; (B) MC/9 mast cells; (C) NFS 60.4 cells; (D) DA 3.15 cells.

Fig 5. RNA blot analysis of GY30 mRNA probed with a GM-CSF cDNA probe. mRNA from the (A) T cell clone Cl.Ly 1+2-/9 (5 µg) or from (B) GY30 cells (10 µg) was run on a 1% agarose-formaldehyde gel and then blotted to a Nytran nylon/nitrocellulose membrane. The filter was hybridized with a ^{32} P-labeled GM-CSF probe prepared as described in Materials and Methods. The autoradiogram was exposed for three days at -70°C using an intensifying screen.

phage colonies observed in the CFU-C assay (Table 1) indicates that, if present, the concentration may be limiting.

GY30 mRNA was analyzed by RNA blot hybridization using molecular probes for several growth factors. The probe for GM-CSF hybridized to a mRNA species that migrated at the same position as the GM-CSF band in a control RNA sample derived from Cl.Ly1+2-/9 T cells (Fig 5). This result clearly establishes that GY30 cells produce GM-CSF. When GY30 mRNA was analyzed with probes for mouse G-CSF, no hybridization could be detected, although later studies (described later) suggest that low levels of G-CSF mRNA are made that are below the level of detection by RNA blotting. In agreement with the results of bioassays of the CM, no hybridization could be detected using probes for IL-2 or IL-3 (data not shown).

LPS stimulation of CSF production. We then wished to determine whether CSF production by GY30 cells could be regulated by various stimulating agents known to activate other lymphoid or hemopoietic cells. In these studies we tested the effects of various concentrations of PHA, PMA, Con-A, and LPS. CM from treated and untreated GY30 cells were collected after 12 hours and tested using the four factor-dependent cell line already described.

Treatment with PMA, Con-A, or PHA had no effect on GY30 cells in any of the assays (data not shown). In contrast, LPS treatment of GY30 cells stimulated increased activity detected by the G-CSF-responsive cell line NFS 60.4 (Fig 6). A total of 20 ng/mL LPS was required to give maximum production of the G-CSF-like activity, and concentrations of 0.02 ng/mL or less had no effect. We calculated that 70 U/mL of G-CSF activity was present in stimulated GY30 supernatant compared with less than 1 U/mL in unstimulated 12-hour supernatant. One unit was defined as the amount of factor that induced half-maximal stimulation of ^3H -thymidine uptake by NFS 60.4 cells under the assay conditions described. LPS titrated into NFS 60.4 cultures at a starting concentration of 200 ng/mL had no effect by itself. Moreover, the addition of various concentrations of LPS to unstimulated 12-hour supernatant did not result in enhanced stimulation of NFS 60.4 cells.

Fig 6. ^3H -thymidine incorporation of NFS 60.4 cells stimulated by supernatants of LPS-treated GY30 cells. A total of 5×10^3 NFS 60.4 cells per culture (total volume of 0.1 mL) were incubated in medium supplemented with varying concentrations of GY30 supernatants induced for 12 hours with LPS at 20 ng/mL ($\square$ — $\square$), 2 ng/mL ($\circ$ — $\circ$), 0.2 ng/mL ($\blacksquare$ — $\blacksquare$), and 0.02 ng/mL ($\triangle$ — $\triangle$) or unstimulated 12-hour GY30 supernatant ($\blacktriangle$ — $\blacktriangle$) or unstimulated GY30 supernatant containing 20 ng/mL LPS ($\bullet$ — $\bullet$). NFS 60.4 cells were also cultured with varying concentrations of purified G-CSF ($\diamond$ — $\diamond$) and LPS ($\diamond$ — $\diamond$). Stock solutions contained 1,000 U/mL G-CSF and 200 ng/mL LPS. Cell cultures were harvested as described in the legend to Fig 4. Results of triplicate cultures are expressed as mean counts per minute $\pm$ SEM.

Our ability to assess the GM-CSF activity of LPS-induced GY30 supernatants was complicated by the fact that certain concentrations of LPS alone directly stimulate proliferation of the DA 3.15 cell line. LPS at concentrations of 2 ng/mL or less does not stimulate DA 3.15 cells, but 2 ng/mL of LPS does stimulate increased production of GM-CSF by GY30 cells (detected by proliferation of DA 3.15 cells, Fig 7). The residual LPS in this sample does not appear to mediate this effect since 2 ng/mL LPS added to an unstimulated supernatant did not cause increased proliferation of the target cells (Fig 7). Stimulation of GY30 cells with 2 ng/mL LPS induced approximately 40 U/mL of GM-CSF, whereas untreated cells produced less than 1 U/mL. None of the supernatants from LPS-treated GY30 cells stimulated IL-2-dependent T cells (HT-2) or IL-3-dependent mast cells (MC/9) (data not shown). Thus, LPS induces increased production of GM-CSF and an activity similar to G-CSF. However, it does not induce new expression of IL-2- or IL-3-like activities.

Recombinant IL-1 enhances CSF production. To determine whether macrophages and T cells secrete molecules that regulate stromal cell function, GY30 cells were cultured with CM of various T cell lines and the macrophage cell line P388D1. Increased levels of CSF activity were found only in supernatants of GY30 cells incubated with P388D1 CM (data not shown). This result raised the possibility that a macrophage product such as IL-1 mediates this effect. Therefore, GY30 monolayers were cultured with varying

Fig 7. [^3H]-thymidine incorporation of DA 3.15 cells stimulated by supernatants of LPS-treated GY30 cells. The general culture conditions were described in the legend to Fig 4. DA 3.15 cells were cultured with varying concentrations of supernatants of GY30 cells treated with LPS at 2 ng/mL ($\square$ — $\square$) and 0.2 ng/mL ($\blacksquare$ — $\blacksquare$), supernatant of unstimulated GY30 cells (Δ — Δ), and unstimulated GY30 supernatant containing 2 ng/mL LPS ($\blacktriangle$ — $\blacktriangle$). DA 3.15 cells were also cultured with 2 ng/mL LPS ($\circ$ — $\circ$) and varying concentrations of recombinant GM-CSF (Δ — Δ). Results of triplicate cultures are expressed as mean counts per minute $\pm$ SEM.

concentrations of recombinant IL-1. Supernatants were harvested after 12 hours and tested in a [^3H]-thymidine incorporation assay using the factor-dependent cell lines. We found that supernatants of GY30 cells treated with 10 U IL-1/mL or more contained at least 210 U/mL of the G-CSF activity (Fig 8A, measured by NFS 60.4 cells) and 230 U/mL of GM-CSF (Fig 8B, measured by DA 3.15 cells). IL-1 at various concentrations had no effect on these cells by itself. Further, the addition of 10 U IL-1/mL to uninduced GY30

Fig 8. IL-1 stimulates increased CSF production by GY30 stromal cells. (A) NFS 60.4 and (B) DA 3.15 cells were cultured with supernatants of GY30 cells treated for 12 hours with 0, 0.1, 1, 10, or 100 U/mL recombinant IL-1. The levels of [^3H]-thymidine incorporation stimulated by these various supernatants and purified G-CSF or GM-CSF were assayed as described in the legend to Fig 4. The stimulatory activities of IL-1-induced GY30 supernatants are expressed in units per milliliter where 1 unit is defined as the amount of factor that stimulates half-maximal [^3H]-thymidine incorporation of the factor-dependent cells.

supernatant did not result in enhanced stimulation of the factor-dependent cell lines. We also found that IL-1-induced GY30 supernatants failed to stimulate HT2 T cells and MC/9 mast cells (data not shown).

These results suggest that IL-1 as well as LPS may up-regulate the production of colony-stimulating activities by the stromal cell line. However, it was necessary to rule out that the induction by IL-1 was due to traces of endotoxin contamination. Since IL-1 added directly into DA 3.15 cell cultures had no effect by itself, we reasoned that any endotoxin contamination must be 2 ng/mL or less. This concentration was already shown to be nonstimulatory for this LPS-responsive cell line (Fig 7). This conclusion was confirmed when IL-1 prepared at 10 U/mL was negative using the limulus amoebocyte lysate test (endotoxin sensitivity of 0.05 to 0.2 ng/mL). Additional evidence was obtained with the stromal cell line HEJ.2 derived from LPS-resistant C3H/HEJ mice. HEJ.2 cells share many properties with GY30 cells including increased production of G-CSF-like activity in response to 10 U/mL IL-1 (Fig 9B, measured by NFS 60.4 cells). In this case, due to the LPS-resistant nature of these cells, LPS concentrations in excess of 3 $\mu\text{g}/\text{mL}$ were required to induce any detectable CSF production within the same 12-hour culture period (Fig 9A). The possibility that the IL-1 preparation was contaminated with these levels of endotoxin was already ruled out by two other means (LPS sensitivity of DA 3.15 cells and the limulus amoebocyte lysate test).

Regulation of CSF mRNA levels by IL-1. mRNA was isolated from GY30 cells 12 hours following the addition of IL-1 and was compared in a RNA blot with mRNA from untreated cells. The results in Fig 10 show that the levels of GM-CSF mRNA are highly inducible by IL-1. The induced mRNA appears to be identical in length to the mRNA produced by uninduced cells or by T cells. These results strongly suggest that IL-1 directly induces new transcription of GM-CSF mRNA in GY30 cells.

We also analyzed GY30 mRNA for G-CSF transcripts using G-CSF cDNA probes. Although no detectable hybridization was found in the mRNA from untreated GY30 cells, mRNA from IL-1-induced cells showed a distinct band of hybridization at approximately the same size previously reported for G-CSF transcripts (1.7 kb).⁴⁹ Based on these results, we believe it is likely that uninduced GY30 cells

Fig 9. LPS and IL-1 stimulate CSF production by HEJ.2 stromal cells. NFS 60.4 cells were cultured with supernatants of HEJ.2 cells treated with (A) 3, 6, 12, and 24 $\mu\text{g}/\text{mL}$ LPS and (B) 1, 10, and 100 U/mL recombinant IL-1. The growth factor activity of the HEJ.2 supernatants, expressed as units per milliliter, was assayed as described in the legend to Fig 4.

Fig 10. (A) Induction of GM-CSF mRNA in GY30 cells by IL-1. mRNA was isolated from untreated GY30 cells or from cells 12 hours following the addition of 100 U/mL of recombinant IL-1. RNA blot analysis was carried out as described in Materials and Methods by using a GM-CSF probe. The autoradiogram was exposed for 16 hours at -70°C using an intensifying screen. The GM-CSF band in uninduced GY30 mRNA requires longer exposure times to be detectable. (B) Induction of G-CSF mRNA in GY30 cells by IL-1. mRNA samples isolated as in (A) were analyzed in RNA blots using two ^{32}P -labeled synthetic oligonucleotides corresponding to residues 68 to 163 and 599 to 694 of the mouse G-CSF cDNA.

produce low levels of G-CSF mRNA undetectable by RNA blotting that account for the NFS 60.4-stimulatory activity.

DISCUSSION

Stromal cells produce GM-CSF and G-CSF. Studies using clonal lines of stromal cells provide a powerful means to understand the mechanisms by which the bone marrow microenvironment regulates stem cell growth and differentiation. Important questions arise as to the nature of the signals mediating interactions between stromal cells and hemopoietic progenitor cells, including the possible production of soluble factors and their relationship to hemopoietic regulators made by cells outside the marrow such as T lymphocytes. Although previous studies have shown that several stromal cell clones produce M-CSF,^{20,33} a few lines apparently secrete additional granulocyte and macrophage colony-stimulating activities.³⁸ Neither the number of factors involved nor their precise identity could be established.

We describe here the characterization of a fibroendothelial-like stromal cell clone, GY30, which was isolated from the adherent layers of bone marrow cultures. GY30 cells sustain through direct contact the production of committed granulocyte-macrophage progenitor cells (GM-CFU) but fail to support the survival of multipotential stem cells as detected by the CFU-5 assay. Further, the supernatant of GY30 cells stimulates the formation of granulocyte-macrophage colonies in semisolid bone marrow cultures. Using a panel of factor-dependent cell lines, we show that no significant levels of IL-3 or IL-2 could be detected in GY30 cell supernatants.

However, results with these cell lines suggest that GY30 cells produce activities similar to GM-CSF and G-CSF. Both factors could be unambiguously demonstrated by the presence of GM-CSF and G-CSF transcripts detected using specific cDNA probes. These results show that GM-CSF, which is made by activated T cells, also plays a role in controlling steady-state hemopoiesis in the bone marrow. Our results also establish that G-CSF, previously shown to be made by peritoneal cells⁵⁶ and by a fibrosarcoma cell line⁴⁹ must also be involved in marrow hemopoiesis.

Production of CSFs by stromal cells is modulated by LPS and IL-1. We provide the first evidence that the production of hemopoietic growth factors by marrow stroma in vitro can be modulated by external factors; the production of both GM-CSF and G-CSF by GY30 cells can be greatly enhanced (70- to 200-fold) by LPS and the cytokine IL-1. Parallels can be drawn between the inducible production of CSFs by bone marrow stromal cells and the inducible expression of CSFs by T cells activated by either antigen or mitogens. In both stromal cells and T cells, the induction of factors is correlated with increased levels of the corresponding mRNAs.

The action of LPS, which we document in vitro, suggests a role for this factor in regulating hemopoietic factor production in vivo. Under steady-state conditions, the bone marrow produces a constant number of various blood cells, but it is not clear what regulatory signals establish the balance between stem cell self-renewal and the maturation of progenitor cells. Nevertheless, it is known that the number of

circulating neutrophilic granulocytes is increased in mice following the administration of bacterial products such as endotoxin. Under these conditions, there are also elevated serum levels of granulocyte-macrophage colony-stimulating activities^{57,58} as well as granulocytic hyperplasia of the bone marrow.⁵⁹ These prior studies suggest that the steady-state production of granulocytes and macrophages by bone marrow can be upregulated in response to bacterial infections. Although it is unclear whether bone marrow is exposed to antigen during most bacterial infections, our results demonstrate that hemopoietic factor production by a bone marrow-derived cell can be augmented directly by the bacterial product, LPS.

The regulatory effects of IL-1 on the stromal cell clone are also consistent with previous studies. In humans, an unidentified factor produced by mononuclear phagocytes was shown to stimulate the production of CSF activities by fibroblasts⁶⁰ and vascular endothelial cells.⁶¹ Because IL-1 production by macrophages and possibly other cell types is elicited by a wide variety of agents, the functional activation of stromal cells by IL-1 could be part of an important

protective mechanism against many types of infection. Furthermore, IL-1 or IL-1-like molecules may also function as normal regulatory signals within the marrow microenvironment. Pure stromal cell populations apparently secrete hemopoietic factors constitutively under standard in vitro culture conditions, but it is not known whether they do so in vivo. It is possible that within the bone marrow microenvironment, stromal cells require endogenous signals such as IL-1 to carry out some of their normal hemopoietic regulatory activities. Thus, all levels of blood cell production might be determined by positive and negative regulation of stromal cell activities.

ACKNOWLEDGMENT

We thank Drs R. Coffman, B. Blumberg, N. Nicola, R. Shaduck, and P. Lomedico for generous gifts of reagents and S. Nagata for sharing information prior to publication. The excellent technical assistance of C. Moulds, L. Ho, and L. Mercer and the patience of J.A. Zahner and G. Burget for typing this manuscript are gratefully acknowledged. We thank Drs D. Zipori, C. Martens, and M. Kehry for helpful criticism of the manuscript.

Oral Contraceptives and Gender Affect Protein S Status

By L.M. Boerger, P.C. Morris, G.R. Thurnau, C.T. Esmon, and P.C. Comp

Protein S is a plasma protein that serves as a cofactor for the anticoagulant effects of activated protein C. Congenital protein S deficiency is often associated with thromboembolic disease. During pregnancy a decrease in the functional and antigenic levels of protein S occurs; this change in protein S status may contribute to the thromboembolic complications that sometimes occur during pregnancy. In certain patients, oral contraceptive use has also been associated with thrombotic complications. In this study, protein S status was determined in 21 women taking oral contraceptives and compared with that of 21 women not taking oral contraceptives and that of 21 men. The results show that women taking oral contraceptives have significantly lower total protein S ($24.3 \pm 3.6 \mu\text{g/mL}$; mean $\pm$ SD) than women not taking oral contraceptives (28.6 ± 3.9

$\mu\text{g/mL}$) ($P < .005$). Men had significantly higher protein S levels ($30.9 \pm 3.9 \mu\text{g/mL}$, $P < .01$) than age-matched women not taking oral contraceptives. In plasma, an equilibrium exists between free (functionally active) protein S and protein S complexed to C4b-binding protein, which is functionally inactive. The mean levels of C4b-binding protein were essentially the same among the three groups, but the levels of free protein S were significantly different and reflected different total protein S antigen levels. Additionally, we found that inflammation significantly elevated C4b-binding protein levels and could result in a further significant decrease in free protein S levels. These data indicate that plasma protein S levels are significantly affected by hormonal status and inflammation.

PROTEIN S is a plasma protein that serves as a cofactor for the anticoagulant effects of activated protein C.¹ In this regard, two observations have been reported: (1) congenital protein S deficiency is associated with recurrent thromboembolic disease²⁻⁴ and (2) a relative protein S deficiency occurs in women during pregnancy.⁵ During pregnancy, functional protein S levels are significantly lower ($38\% \pm 17\%$; mean $\pm$ SD) than those found in age-matched, non-pregnant women ($97\% \pm 32\%$; $P < .001$).⁵ The reduced functional protein S levels are accompanied by a significant reduction in total protein S antigen to $68\% \pm 11\%$ ($P < .001$). Based on these data, we postulated that these changes in protein S status are among the factors that predispose pregnant women to thromboembolic complications.

Since oral contraceptive (OC) use hormonally mimics pregnancy and has been associated with thrombotic complications,⁶ we have evaluated OC users to determine whether significant changes in protein S status occur. Since sex hormonal differences could affect protein S levels, we have evaluated the protein S status of healthy males as well.

In normal individuals approximately 40% of protein S is found free in plasma, and 60% is complexed to C4b-binding protein (C4b-BP), an inhibitor of the complement system.⁷

The free protein S is functionally active, and the complexed form is inactive.^{8,9} Because changes in the C4b-BP level may affect the distribution of protein S in plasma, C4b-BP levels along with free protein S and total protein S antigen levels were measured.

MATERIALS AND METHODS

Immunologic assays. Total protein S antigen and free protein S assays were performed as previously described.^{5,8} Purified protein S, prepared as previously described,³ was used to construct a standard curve. Crossed immunoelectrophoresis⁸ was used to estimate the free protein S in the patients with acute infections. C4b-BP levels were determined by a radioimmunoassay involving the displacement of ¹²⁵I-C4b-BP from an immobilized monoclonal antibody directed against C4b-BP, which has been previously characterized.⁵ To perform the assay, C4b-BP was purified as described¹⁰ and was radiolabeled with ¹²⁵I by the iodogen method¹¹; the ¹²⁵I-C4b-BP had a specific activity of $8 \mu\text{Ci}/\mu\text{g}$. Monoclonal antibody (designated BP45) directed against C4b-BP was bound to Immunobeads (Bio-Rad Laboratories, Richmond, CA) according to the manufacturer's directions; approximately $100 \mu\text{g}$ antibody was bound per milliliter of beads. A standard curve of C4b-BP ranging from 0.6 to $0.0375 \mu\text{g/mL}$ was prepared in 20 mmol/L Tris buffer, pH 7.4, containing 150 mmol/L NaCl and 10 mg/mL serum bovine albumin (Sigma Chemical Co, St Louis). To initiate the assay, $50 \mu\text{L}$ of a 1:100 dilution of patient plasma in Tris/saline/albumin buffer, $50 \mu\text{L}$ of the Tris/saline/albumin buffer containing 10,000 cpm of ¹²⁵I-C4b-BP, and $50 \mu\text{L}$ of BP45 immunobeads suspended in 20 mmol/L Tris, pH 7.4, containing 150 mmol/L NaCl were pipetted sequentially into a 1.5-mL micro test tube (Bio-Rad Laboratories), mixed on a vortex mixer, and incubated at 25°C for two hours. The beads were then suspended in 1.2 mL 20 mmol/L Tris, pH 7.4, containing 2 mol/L NaCl and vortexed, and the beads were removed from suspension by centrifugation in a Microfuge B (Beckman Laboratories, Palo Alto, CA) for two minutes. Unbound antibody was removed by aspiration and the wash step repeated twice. After the final wash, bound ¹²⁵I-C4b-BP was quantitated in a gamma counter (Nuclear Enterprises, Edinburgh). The C4b-BP content in patient samples was calculated from the standard curve. All samples were run in triplicate. The same-day variation was 8%, and the between-day variation was 11%.

Patients. Twenty-one women with a mean age of 27 years (range between 17 and 49 years) who were taking a single OC formulation for more than 6 months were studied. The formulations

involved were as follows: 1 mg norethindrone plus 0.05 mg mestranol (seven women), 1 mg norethindrone plus 0.035 mg ethinyl estradiol (three women), 0.5 mg norethindrone plus 0.035 mg ethinyl estradiol (one woman), 1 mg ethynodiol diacetate plus 0.05 mg ethinyl estradiol (three women), 1 mg norethindrone plus 0.05 mg mestranol (one woman), 1 mg norethindrone plus 0.035 mg ethinyl estradiol (four women), triphasic 0.05 to 0.125 mg levonorgestrel plus 0.03 to 0.04 mg ethinyl estradiol (one woman), and 1 mg ethynodiol diacetate plus 0.1 mg mestranol (one woman). Twenty-one women not taking OC (mean age, 33.4 years; range, 22 to 64 years) and 21 men (mean age, 33.8 years; range, 18 to 53 years) were also studied. None of the 63 participants had a personal or familial history of thromboembolic disease.

In addition, the protein S status of six men and two women with severe infections were studied and the results compared with those of sex- and age-matched, healthy controls. Two of the patients had cellulitis, four had bacterial pneumonia, and two had pyelonephritis. All patients had WBC counts of 13,500 or above. All study subjects gave informed consent.

Statistical analysis. Levels of both protein S and C4b-BP in women taking OC were compared with those of men as well as those of women not taking OC by means of Student's *t* test.

RESULTS

Women taking OC had a mean total protein S level of $24.3 \pm 3.6 \mu\text{g/mL}$ (mean $\pm$ SD) with a range of 20.0 $\mu\text{g/mL}$ to 29.6 $\mu\text{g/mL}$. This is significantly lower than the $28.6 \mu\text{g/mL} \pm 3.9 \mu\text{g/mL}$ (range, 21.0 $\mu\text{g/mL}$ to 35.8 $\mu\text{g/mL}$) found in women not taking OC ($P < .005$). Men had significantly higher levels of total protein S ($30.9 \mu\text{g/mL} \pm 3.9 \mu\text{g/mL}$; range, 23.7 $\mu\text{g/mL}$ to 42.0 $\mu\text{g/mL}$) than did the women not taking OC ($P < .01$).

The C4b-BP levels were not significantly different among the three groups examined: $244 \mu\text{g/mL} \pm 98 \mu\text{g/mL}$ (mean $\pm$ 1 SD) for women not taking OC, $253 \mu\text{g/mL} \pm 95 \mu\text{g/mL}$ for men, and $233 \mu\text{g/mL} \pm 105 \mu\text{g/mL}$ for women taking OC.

The observed differences in the total protein S antigen levels and the similar C4b-BP levels found in the three groups suggested that the free protein S levels might be significantly different. This was found to be the case. Women taking OC had $86\% \pm 17\%$ free protein S (mean $\pm$ SD) compared with the free protein S in a normal pooled plasma control, which was significantly lower ($P < .1$) than the levels found in women not taking OC ($90\% \pm 20\%$). The free protein S levels were significantly higher ($P < .005$) in men at $109\% \pm 20\%$ compared with the levels found in women not taking OC.

The thromboembolic complications of OC use are often associated with periods of physiological stress such as the postoperative period¹² and during episodes of trauma and infection.¹³ If C4b-BP levels were elevated during physiological stress (ie, an acute-phase reactant), this could shift the protein S to the complexed form by the law of mass action. This shift in protein S could further compromise the already reduced levels of free protein S found in the OC users and might be a further predisposing factor to thrombosis. The eight patients with acute infection had a mean C4b-BP level of $370 \mu\text{g/mL} \pm 66 \mu\text{g/mL}$, which was significantly higher ($P < .005$) than the mean level of $240 \mu\text{g/mL} \pm 62 \mu\text{g/mL}$ found in eight age- and sex-matched controls. Five of the eight patients had reduced free protein S levels as estimated

by crossed immunoelectrophoresis and mildly reduced total protein S antigen (23.4 $\mu\text{g/mL}$ v 27.8 $\mu\text{g/mL}$ in controls, not significant).

DISCUSSION

The 18% decrease in total protein S associated with OC administration appears to be relatively small. However, since protein S is distributed in plasma in two forms (free protein and complexed with C4b-BP), such a decrease in total protein S may be calculated⁵ to result in a 24% decrease in the free protein S level. Based on this calculation, we believe that particular care should be taken in prescribing OC to women who have decreased protein S levels on a congenital basis and to women who have elevated levels of C4b-BP as a result of a chronic inflammatory process. In the former, the already low protein S levels might be decreased even further by a hormonal effect of OC administration. In the latter case, the elevation of C4b-BP level accompanying the inflammatory process would favor a shift in protein S to the complexed, inactive form. In this situation, a further reduction in total protein S antigen due to the hormonal changes secondary to OC could result in an enhanced reduction in free protein S. To determine the actual contribution of the protein S system to the thrombotic complications of OC use, prospective study will be required.

The 54% increase of the C4b-BP level observed in patients with acute infections suggests that C4b-BP may be an acute phase reactant. This significant increase in C4b-BP levels would significantly affect the distribution of protein S in plasma and would result in a 40% decrease in the free protein S level.⁵ Such a drop in the concentration of free protein S might predispose the patient to thrombosis, especially when other concomitant factors predisposing to thrombosis such as stasis or recent tissue trauma are present.

Finally, the 8% increase in total protein S and the 21% increase in free protein found in men compared with women not taking OC suggests that different normal ranges for these parameters be considered for men and women. This may prove to be of particular value in the definition of the lower limit of the normal range where significant overlap between normal and congenitally protein S-deficient populations may occur.

ACKNOWLEDGMENT

The authors thank Randy Nixon for preparing the C4b-BP used in the radioimmunoassay and thank Deborah Doray for her excellent technical assistance. The generous assistance of the Oklahoma Blood Institute in obtaining plasma samples is also appreciated. We thank Barbara Irish for her help in the preparation of this manuscript.

Modulation of Endothelial Cell Functions by Different Molecular Species of Interleukin 1

By E. Dejana, F. Breviario, A. Erroi, F. Bussolino, L. Mussoni, M. Gramse, G. Pintucci, B. Casali, C.A. Dinarello, J. Van Damme, and A. Mantovani

Different molecular species of interleukin 1 (IL 1) were examined for the spectrum of responses elicited in human endothelial cells (HEC), including synthesis of prostacyclin (PGI₂), tissue-type procoagulant activity (PCA), platelet activating factor (PAF), and plasminogen activator inhibitor (PA-I). The IL 1 preparations utilized for the present study included a natural, partially purified IL 1, a preparation purified to homogeneity with extensive homology with the derived aminoacid IL 1 β (p17) sequence denominated "22K factor," murine recombinant IL 1 α , human recombinant IL 1 α (p15) and β (p17). Natural, partially purified IL 1, a mixture of α and β species, induced the entire spectrum of

responses in HEC. Production of PA-I was elicited by all forms of IL 1 tested. PGI₂ and PCA were elicited by "22K factor" and by human recombinant IL 1 β and α but not by murine recombinant IL 1 α . PAF synthesis was stimulated by murine and human recombinant IL 1 α but not by human recombinant IL 1 β and 22K factor. Thus the available different molecular forms of IL 1 elicit largely but not completely overlapping patterns of responses in HEC. The IL 1 pathway of regulation of HEC functions might provide a basis for novel strategies in therapeutically oriented research on vessel wall disorders.

SOLUBLE products released by lymphocytes and macrophages are potent regulators of various functions of vascular cells, such as proliferation, migration, production of colony stimulating factors, and expression of class II histocompatibility (Ia) antigens.¹⁻⁶

Specifically, the activated monocyte product interleukin 1 (IL 1) has been reported to induce multiple responses in human endothelial cells (HEC).⁷ Others and our group have recently shown that this monokine induces prostacyclin (PGI₂)⁸⁻¹⁰ and platelet activating factor (PAF)¹¹ synthesis in endothelial cells (EC) from human umbilical vein. Bevilacqua et al¹² established that IL 1 stimulates expression of a tissue factor-like procoagulant activity (PCA); increase in plasminogen activator inhibitor (PA-I) production by HEC after IL 1 was also observed.¹³

IL 1 is a family of polypeptides, biochemically heterogeneous but with some common biological properties.¹⁴ At least two dissimilar human gene products have been cloned with limited homology, denominated α (p15) or β (p17).¹⁵⁻¹⁷ One murine IL 1 molecular species was also cloned and appeared to be closely related to the corresponding human α IL 1 form, with 62% matching and 93% conserved sequences.^{18,19}

IL 1 has pleiotropic effects, its targets including immunocompetent cells, liver, central nervous system (CNS), synovia, bone, and muscle.²⁰ The multiplicity of the biological activities attributed to IL 1 and the heterogeneity of the components of the IL 1 family raise the question of whether distinct molecules have distinct biological roles. Attempts to relate different molecular species to the diverse effects of IL 1 on a series of tissues and cellular targets have largely failed. Wood and co-workers were able to dissociate the effect of human IL 1 α v IL 1 β on the stimulation of PGE₂ production by porcine synoviocytes. However, intraspecies differences on the activities of the different molecules of IL 1 have not been described.²¹ Here we tested the activity of the series of IL 1 molecules so far available, including recombinant preparations, on HEC. We report that the different molecules elicit a largely but not completely overlapping spectrum of responses on these cells.

MATERIALS AND METHODS

IL 1 preparations. IL 1 preparations utilized for the present study included:

1. A commercially available purified preparation obtained from *Staphylococcus albus*-stimulated human monocytes and purified by affinity chromatography employing immobilized rabbit antibodies and gel filtration (Ultrapure IL 1, Genzyme, Boston)²²; we will refer to this material as human natural IL 1 (hnIL 1).
2. A pure preparation from mitogen-stimulated human mononuclear cells, purified to homogeneity; the N-terminal aminoacid sequence of this material, referred to as "22K factor," has been described²³ and shows extensive homology with the derived aminoacid IL 1 β sequence.
3. Murine recombinant IL 1 (lot 14430-21) from the P388 D₁ cell line¹⁸ was a kind gift of Dr Lomedico (Roche Institute, New York). Since this clone shows extensive homology with the human IL 1 gene designated α ,^{17,19} we will refer to this material as murine recombinant IL 1 α (mrIL 1 α). This preparation had a specific activity of 10⁵

U/ μ g as evaluated by the costimulatory assay on thymocytes, as described below, and contained 0.23 μ g/U guanidine.

4. Human recombinant IL 1 (p17) expressed in *Escherichia coli* from aminoacid 71-269¹⁵ homologous to a subsequently isolated clone designated β .¹⁶ We will refer to this as human recombinant IL 1 β (hrIL 1 β). The specific activity of this preparations was 2×10^2 U/ μ g.

5. Human recombinant IL 1 α (p15)¹⁶ (hrIL 1 α) was kindly supplied by Dr Gillis (Immunex, Seattle). The specific activity was 10^5 U/ μ g.

IL 1 preparations contained no detectable endotoxin as assessed by the negative Limulus assay on samples containing 100 U/mL of IL 1. IL 1 activity was evaluated in a costimulatory assay with C3H/HeJ thymocytes as responding cells and phytohemagglutinin (0.5 μ g/mL) as stimulus.⁸ A partially purified IL 1 preparation²⁴ was assigned a value of 1,000 U/mL and used as standard in each assay.

Results from triplicate cultures were plotted on a linear regression against the standard preparation and expressed as half maximal U/mL.

Cells. Human umbilical vein endothelial cells were isolated and cultured in medium 199 supplemented with 20% newborn calf serum as previously described in detail.²⁵ The cells were used at the first passage at confluence. After the growth medium was removed the cells (2.5 to 3.5×10^5 cells in a 4 cm² culture well) were washed once with 1 mL phosphate buffer saline (PBS) and incubated at 37 °C with 600 μ L of culture medium in the presence or absence of increasing concentrations of the IL 1 preparations. The time of incubation required to obtain maximal stimulation for each activity was selected on the basis of earlier time-course experiment.^{8,11-13}

Prostacyclin (PGI₂). PGI₂ production was evaluated in the cell supernatant after 24-hour incubation with IL 1. After this period the supernatants were removed from the culture wells, filtered, and stored at -20 °C until tested for 6-keto-PGI₂, the stable PGI₂ metabolite. 6-keto-PGF1 α was measured by a radioimmunoassay (RIA) as previously described in detail.²⁶ Analysis by thin layer chromatography and mass spectrometry²⁵ showed that these cells produce 6-keto-PGF1 α as the main arachidonic acid metabolite.

Platelet activating factor (PAF). PAF was measured in the cell extract after six-hour incubation with IL 1 by biological assay after thin layer chromatography purification, as described previously in detail.¹¹ The product was identified as PAF by its behavior in chromatographic systems, the recovery of biological activity, the physicochemical properties, and susceptibility to lipases.¹¹

Procoagulant activity (PCA). PCA was evaluated in the cell extract after four-hour incubation with IL 1 by a standard one-stage clotting assay (plasma recalcification) as described.²⁷ The standards for the coagulation assay were a 1:10 dilution of rabbit brain thromboplastin. Procoagulant activity in the cell extract was expressed in units of thromboplastin per milligram protein. The type of procoagulant activity was identified using human plasmas selectively deficient in factors II, VII, IX, or X (MERZ-DADE, Duding, Switzerland). Further characterization was performed by the use of known inhibitors of cell procoagulants, namely cysteine protease inhibitors HgCl₂ and iodoacetamide (Sigma Chemical, St. Louis).

Plasminogen activator inhibitor (PA-I). PA-I activity was determined after 24-hour incubation as the capacity of the cell extract to inhibit plasminogen activator-induced plasmin generation in a spectrophotometric assay employing a chromogenic substrate for plasmin as described previously.²⁸

RESULTS

All five IL 1 preparations had IL 1 activity as defined by their ability to stimulate the proliferation of thymocytes in

the presence of phytohemagglutinin (data not shown). The half maximal units of IL 1 for the various preparations were calculated relative to an IL 1 preparation utilized in one of the collaborating laboratories²⁴ (AE and AM). Subsequent comparisons were made on the basis of the concentrations of these agents, which were equally active in the mouse thymocyte costimulatory assay. It has to be mentioned that as evaluated from this test the specific activity of mrIL 1 α was 10^5 U/ μ g protein; of hrIL 1 α , 10^5 U/ μ g; and of hrIL 1 β , 2×10^2 U/ μ g. Thus we had to use 500 times more hrIL 1 β to obtain concentration equally active on the thymocyte costimulatory assay. We have previously reported⁸ that hnIL 1 increased PGI₂ synthesis in vascular cells at concentrations ranging from 1 to 10 U/mL. These observations were now extended to homogenous natural human IL 1 ("22K factor"), hrIL 1 β , and hrIL 1 α (Fig 1). In contrast, mrIL 1 α at concentrations as high as 100 units/mL (corresponding to 1 ng/mL) did not elicit production of PGI₂ in HEC, as shown by the experiment presented in Fig 1.

A similar pattern was observed when PCA was examined (Fig 2). The homogeneous "22K factor," hrIL 1 β , and hrIL 1 α stimulated synthesis of PCA as efficiently as hnIL 1, whereas mrIL 1 α was ineffective at concentrations as high as 100 U/mL.

We have recently observed that hnIL 1 and mrIL 1 α elicited PAF production in HEC.¹¹ As shown in Fig 3, besides hnIL 1 and mrIL 1 α , hrIL 1 α was also an effective inducer of cell-associated PAF in HEC, whereas the "22K factor" had no such activity up to 60 U/mL and hrIL 1 β showed statistically significant activity only at concentrations as high as 100 U/mL (corresponding to 500 ng/mL). HnIL 1, mrIL 1 α , and "22K factor" stimulated production of PA-I in HEC in a comparable way (Fig 4). Since mrIL 1 α failed to induce PGI₂ production and PCA in HEC (see above), it was important to assess whether this preparation contained inhibitors of IL 1-elicited response.

Therefore we incubated HEC for four hours at 37 °C with 50 U/mL of mrIL 1 α mixed with 5 U/mL of 22K factor and measured the PCA produced by these cells. When the cells

Fig 1. Effect of hnIL 1, mrIL 1 α , hrIL 1 α , "22K factor," and hrIL 1 β on 6-keto-PGF 1 α production by HEC. The numbers below the columns indicate the U/mL of the IL 1 forms, as calculated from the thymocyte costimulatory assay as described in the text. The black column reports the control mean value of 6-keto-PGF1 α produced in the absence of IL 1. The values are means $\pm$ SEM of four separate experiments. In each experiment all the IL 1 molecular species were tested on the same cell culture. * $P < 0.01$ v control values by Dunnett's test.

Fig 2. Effect of hnIL 1, mrIL 1 α , hrIL 1 α , "22K factor," and hrIL 1 β on HEC procoagulant activity. The numbers below the columns indicate the U/mL of the IL 1 forms, as calculated from the thymocyte costimulatory assay. The black column reports the control mean value of PCA produced in the absence of IL 1. The values are means $\pm$ SEM of three separate experiments. were stimulated by the "22K factor" alone, the PCA produced was 22.8 ± 3 U/10⁴ cells; mrIL 1 α induced 1.4 ± 0.1 U/10⁴ cells and the combination of the two agents 18.9 ± 3 U/10⁴ cells (the values are means $\pm$ SEM of four replicates, and the results were similar in one additional experiment). It is concluded that the mrIL 1 α preparation does not interfere with "22K factor" activity on PCA production. In addition, since mrIL 1 α contained 0.23 μ g of guanidine per unit, HEC were incubated with up to 12 μ g/mL guanidine alone or in combination with 10 U/mL of hnIL 1; no effects on HEC production of PGI₂, PAF, PCA, or PA-I were observed.

DISCUSSION

The first aim of the present study was to assess whether the modulation of endothelial cell functions by IL 1, which was described by using crude or natural partially purified IL 1, was also effected by purified recombinant molecules. Human natural IL 1 elicited the entire spectrum of HEC responses examined in the present study, thus confirming previous observations.^{8,11-13} This preparation contains the different species, α (p15) and β (p17), of IL 1.²² In contrast, when recombinant IL 1 molecules (or natural material purified to homogeneity in the case of "22K factor") were examined, differential responses were elicited by the dif-

Fig 3. Effect of hnIL 1, mrIL 1 α , hrIL 1 α , "22K factor," and hrIL 1 β on PAF production by HEC. The numbers below the columns indicate the U/mL of the IL 1 forms as calculated from the thymocyte costimulatory assay. The black column reports the control mean value of PAF produced in the absence of IL 1. The values are means $\pm$ SEM of four separate experiments. In each experiment all the IL 1 molecular species were tested on the same cell culture. * P < 0.05; ** P < 0.01 v control values by Dunnett's test.

Fig 4. Effect of hnIL 1, mrIL 1 α , "22K factor," and hrIL 1 β on PA-I production by HEC. The number below the columns indicate the U/mL of the IL 1 forms as calculated from the thymocyte costimulatory assay. The black column reports the control mean value of PA-I produced in the absence of IL 1. The values are means $\pm$ SEM of three separate experiments. ferent molecular species examined. All the IL 1s tested induced synthesis of PA-I in HEC. Murine recombinant IL 1 α stimulated the synthesis of PAF in HEC but was consistently inactive in inducing PGI₂ and PCA. Murine recombinant IL 1 α is highly homologous to the human α species.^{17,19} However, in contrast to the murine α species, human recombinant IL 1 α stimulated PCA and PGI₂ synthesis (in the limited number of assays in which we could test this particular IL 1).

We examined the effects on HEC of two preparations of IL 1 β , a natural purified material ("22K factor") and a recombinant preparation. Both IL 1 β preparations elicited the entire spectrum of HEC responses examined with the possible exception of PAF: induction of PAF was only observed with recombinant IL 1 β at a concentration of 100 U/mL, corresponding to 500 ng/mL. Under the same conditions murine recombinant IL 1 α induced PAF at 1 U/mL corresponding to 0.01 ng/mL as previously reported.¹¹ Thus IL 1 β seems to be 100 (on a U/mL basis) or 50,000 (on an ng/mL basis) times less effective than the α species.

The apparently different response of HEC to α and β IL 1 species for PAF production is the first evidence of an intraspecies functional dissociation between these two IL 1 forms in the same cell type. The observation that hnIL 1 stimulates PAF synthesis excludes the possibility of a peculiar effect related to the recombinant nature of the two α species. Conversely the lack of effect of the β forms of IL 1 does not seem to be simply related to their lower activity on HEC, as demonstrated by their effectiveness on the other HEC functions tested. Thus the data presented here indicate that different molecular species of IL 1 elicit largely but not completely overlapping patterns of responses in HEC.

The in vivo response to partially purified IL 1 assessed by fever, neutrophilia, changes in plasma divalent cations, or fibrinogen concentrations, differs in various animal species^{29,30}; furthermore, biochemically distinct IL 1 prepara-

tions can be differently affected by these species-related restrictions. It has not been elucidated whether these differences reflect the presence of target organ-specific inhibitors in the preparations, differences in the *in vivo* bioavailability, or different cell susceptibility. Through the analysis of the activities of four distinct preparations of human IL 1 separated by size or charge, Wood and co-workers²¹ observed no clear-cut differences among them, with the exception that the stimulation of PGE₂ production by pig synoviocytes was only induced by the PI 5.5, 15,000 Kd mol wt IL 1 preparation. These authors considered the possibility of the presence of inhibitors in the inactive preparations. However, the slight inhibitory activity observed in some of the IL 1 preparations was not strong enough to completely account for their apparent inactivity.

In this paper the peculiar spectrum of responses elicited by mrIL 1 α , in respect to the hrIL 1 α , might be related to the murine origin of this clone and suggests that slight differences in the molecular structure may greatly affect functional properties.

In conclusion, the results presented here show that molecules with IL 1 activity have some selectivity in effects on HEC functions and emphasize the potential complexity of the fine regulation of leukocyte-vessel wall interactions. The HEC activities considered in this study, ie, PGI₂, PCA, PAF and PA-I, might be important in the modulation of vascular tone and thrombus formation. In particular, PAF produced by IL 1-stimulated HEC is mostly cell associated¹¹ and appears to be appropriately located to interact with adjacent leukocytes and eventually platelets and to promote their activation. The IL 1 pathway of regulation of these HEC functions could thus provide a basis for novel strategies in therapeutically oriented research on vessel wall disorders.

ACKNOWLEDGMENT

We thank Dr P. Lomedico for stimulating and helpful discussions; M.J. Buchanan, McMaster University, Hamilton, Ontario, Canada, for the antibody to 6-Keto-PGF 1 α ; Vanna Pistotti, Judith Baggott, and Vincenzo and Felice de Ceglie for their help in preparing the manuscript.
